- If there is no suspicion for residual infection, the distal femur, proximal tibia, and patella are prepared for reimplantation of the components, and the knee is balanced to achieve symmetric flexion and extension gaps.
- Depending on the degree of bone loss encountered, metal augments, stems, porous cones, or sleeves may be needed to reconstruct the bony defect.

Positioning

- Supine
- Tourniquet applied to the thigh
- Bump under ipsilateral hip to internally rotate the operative leg
- Povidone-iodine (preferred) or chlorhexidine skin prep

Approach

- Medial parapatellar approach: most commonly used approach for septic arthritis of the knee and open periarticular fractures with excellent exposure to anterior structures of the knee
- Landmarks: borders of the patella, tibial tubercle
- Longitudinal midline or medial incision, extending proximally to 5 cm above superior pole of patella and distally to tibial tubercle depending on desired exposure
- Develop skin flaps to expose interval between vastus medialis obliquus and quadriceps tendon proximally, medial border of patella, and medial border of patellar tendon distally
- Medial parapatellar arthrotomy performed sharply or using cautery
- Depending on amount of exposure needed, patella can be dislocated and flipped laterally to provide access to lateral joint structures.

TECHNIQUES

■ Bone Infection Management

- The goal of bony debridement in all of these conditions is to resect all bone that is necrotic or contaminated with potential biofilm formation.
- Debridement is typically accomplished with rongeurs, curettes, and osteotomes, as well as round or pencil tipped high-speed burs.
 - The bur can be especially useful for quick debridement of the bone or removing a well-fixed implant and cement.
- The debridement should continue until punctate bleeding bone is encountered.
 - To allow this, a tourniquet should not be inflated during the debridement, if possible.
- Bony resection may be extensive and can create dead space and structural instability (**TECH FIG 1A,B**).
- Antibiotic impregnated PMMA cement may be used to temporarily manage dead space and deliver antibiotics to the local tissues (**TECH FIG 1C**).
- Bone loss management is beyond the scope of this chapter but includes the following techniques: induced membrane technique, allograft reconstruction, autograft reconstruction including vascularized fibula, bone transport and distraction osteogenesis, and primary shortening of the limb.

TECH FIG 1 • **A.** Bicompartamental knee arthroplasty being removed for chronic periprosthetic infection. **B.** Knee after extensive bony debridement and tibial

tubercle osteotomy required for removal of a chronically infected total knee arthroplasty. **C.** Radiograph showing an antibiotic-impregnated polymethylmethacrylate spacer placed after removal of an infected total knee arthroplasty in the first of a planned two-stage procedure.

■ Soft Tissue Infection Management

Irrigation and Debridement

- Although there is no consensus, a high volume of low-pressure irrigant appears to be sufficient, such as with gravity irrigation using cystoscopy tubing.
 - High-pressure irrigation, though potentially beneficial for removing more bacteria and debris with less solution, may cause damage to soft tissues and the bone.
 - Pulsatile devices have also not been shown to improve outcomes compared to gravity irrigation and may actually have a decreased irrigation rate overall.
 - Bulb irrigation may not be as efficacious.
- Normal saline is the favored irrigant, with or without the use of added antibiotics in the final liter of irrigation.
 - In the setting of open fractures with a traumatic arthrotomy, the amount of irrigant used generally depends on the extent of injury. For example, employing the Gustilo classification, type I injuries can be effectively irrigated with 3 L of saline, type II with 6 L, and type III with 9 L.
- In open fractures, debridement should involve a systematic inspection of all tissue types, including the skin, subcutaneous fat, fascia, muscle, and bone.
 - Remove all necrotic tissue until a healthy bleeding wound bed is achieved.
 - Muscle viability can be determined by color, contractility, consistency, and capacity to bleed.
 - Debridement should be performed sharply, centripetally, and radically, removing any tissue that may even appear questionably viable.
 - The cortical bone without soft tissue attachments should be removed, as it will be nonviable, though articular fragments should be retained if joint

reconstruction can be achieved (**TECH FIG 2**).

- A repeat debridement can be performed after 24 to 48 hours if tissue viability or adequacy of initial debridement is in question and at the time of definitive closure in wounds requiring a muscle flap.

TECH FIG 2 • The knee in **FIG 1** after debridement and placement of an articulating spacer made from antibiotic-impregnated PMMA.

Adjuncts

- Hydrogen peroxide
 - May be synergistic in conjunction with chlorhexidine or povidone-iodine with regard to bactericidal activity
 - Can result in wound complications, local cytotoxicity against healthy tissue, and increase risk of air embolism
- Local antibiotics
 - Antibiotic-loaded polymethylmethacrylate (PMMA, bone cement): vancomycin and aminoglycosides, such as tobramycin and gentamicin, can be effectively incorporated during mixing process and are thermostable to withstand the exothermic polymerization of the cement.
 - Can be formed into beads and placed into wound bed
 - Implants used for fracture fixation can be coated for delivery to tissues.
 - Antibiotic powder placed directly into wound
- Negative pressure wound therapy
 - Has a role in wounds left open or closed primarily
 - Reduces edema

- Improves local microcirculation
- Can be used to stage coverage for open wounds requiring delayed flap closure

PEARLS AND PITFALLS

Bone management	■ Do not strip viable bone. Remove all stripped bone not attached to cartilage as these represent a nidus for future infection.
Soft tissue management	■ Maintaining or reconstructing a viable and well-vascularized soft tissue envelope in the case of open fractures is key to preventing infection and enhancing bone healing. Maintain all viable bone. Do not pinch the skin. Use atraumatic technique.
Necrotic tissue	■ Remove all hardware and nonviable tissue as these represent a nidus for future infection.
Cartilage	■ Preservation of metaphyseal and periarticular fragments stripped of soft tissue is the exception as they may reintegrate in contrast to diaphyseal fragments and may be critical to reconstructing the joint line or articular surface.
Negative pressure wound dressing	■ Do not apply over bone directly as it can desiccate the location that requires further debridement. Do not apply in active infection.
Antibiotic beads	■ Consider for temporary management of an infected wound bed.
Well-fixed implant	■ Cemented implants should be carefully freed from the underlying cement with a bur or saw before attempted removal to avoid fracture of key supporting structures.
Amputation	■ If reconstruction and preservation of the limb are not feasible, amputation should be strongly considered.
Wound edges	■ Debride rounded skin to fresh edges to facilitate healing.
Plastic surgery	■ Consult plastic surgery early in the process of wound closure or defect management to assess primary, secondary, or flap-based closure.

POSTOPERATIVE CARE

- Open fractures
 - Antibiotics should be administered for 24 hours after definitive closure of the wound.
 - The weight-bearing status of the patient will depend on the type of fixation used and location of the injury.
 - Diaphyseal fractures treated with intramedullary nailing can typically be treated with weight bearing as tolerated, whereas periarticular fractures require several weeks of nonweight bearing to allow anatomic healing of the articular surface.
 - Early mobilization of neighboring joints is critical to prevent adjacent stiffness.
- Osteomyelitis
 - Intravenous antibiotics for at least 6 weeks is typically required with the choice depending on the sensitivities of the identified microorganism.
 - ESR and CRP levels are monitored at routine intervals.
 - Early mobilization of the patient and maintaining motion at adjacent joints is similarly critical to overall functional outcome.
- Infection after TKA
 - Intravenous antibiotics specific to the organism are continued for a minimum of 6 weeks after the initial debridement and explanation until ESR and CRP levels have resolved.
 - After the patient has completed antibiotic therapy, the ESR and CRP are evaluated at least 2 weeks later.
 - Reimplantation is then considered only if the ESR and CRP levels are normal.

OUTCOMES

- Open fractures
 - Successful treatment of open fractures depends on the thoroughness of the debridement, the presence of a well-vascularized soft tissue envelope, and the bony reconstruction.
 - The overall infection rate for open fractures has been shown to be around 2% to 4%, whereas Gustilo type IIIC injuries can become infected at rates as high as 20% to 40%.^{7,8}
 - In open fractures treated with antibiotics at the time of admission, there is no

significant difference in infection rates when debrided within or after 6 hours of injury.

■ Osteomyelitis

- Units experienced in the treatment of osteomyelitis typically achieve the best outcomes.
- Cierny reported a cure rate of 84% at 2 years of follow-up.⁹

■ Infection after TKA

- Eradication of infection following two-stage protocol using an antibiotic spacer followed by reimplantation has reported success rates between 74% and 91%.
- The data on articulating vs static spacers are conflicting; however, some studies have shown improved patient satisfaction, range of motion, and an easier exposure at the time of reimplantation when an articulating spacer is used.

COMPLICATIONS

- Open fractures can result in infection and osteomyelitis, nonunion, malunion, hardware failure, and amputation.
- Inadequate treatment of osteomyelitis can lead to persistent infection, sinus formation, and malignant transformation.
- Osteomyelitis may also require amputation.
- Inadequate treatment of PJI can lead to persistent infection or reinfection requiring repeat debridement and antibiotic spacer exchange, chronic suppression with antibiotics if the patient is not a surgical candidate, or amputation.

31 Bone Reconstruction of the Knee

CHAPTER

Robert J. Steffner and Raffi S. Avedian

DEFINITION

- For this chapter, we will be discussing segmental bone loss with a specific example of a metadiaphyseal hemicortical bone defect below an intact knee joint.
- Above and below the knee is a common area for segmental bone loss due to trauma, tumor, and infection.
- Bone loss in the proximal tibia with an intact joint that compromises the extensor mechanism is often best reconstructed with an intercalary fresh frozen allograft with soft tissue attachments. This facilitates extensor mechanism reconstruction.
- Joint loss is generally reconstructed with an allograft-prosthetic composite or endoprosthetic reconstruction.

ANATOMY

- Anatomy relevant to reconstruction on the medial knee includes the adductor tendon insertion on the medial distal femur and the pes anserinus tendons inserting on the proximal tibia. The surgeon will encounter the femoral artery and vein just below the medial intermuscular septum moving through the adductor hiatus to enter the popliteal fossa.
- Pay close attention to identify and preserve the saphenous nerve branch and saphenous vein.
- The medial collateral ligament (MCL) connects the medial distal femur to the medial proximal tibia. The deep portion of the ligament inserts on the proximal tibia approximately 1 cm below the joint line. The superficial portion is broad and inserts on the proximal tibia 6 to 7 cm distal to the joint line.

- The MCL may need to be reconstructed as part of the surgical procedure.
- On the lateral knee, the iliotibial band inserts on the proximal lateral tibia at Gerdy tubercle and the bicep femoris tendon spans the knee to insert onto the fibular head. Posterior to the bicep femoris tendon lies the common peroneal nerve. The nerve divides at the anterior fibular neck into deep and superficial branches.
- The lateral collateral ligament connects the lateral distal femur to the fibular head. Reconstruction may be required with bone defect management at the lateral knee.
- Soft tissue loss around the proximal tibia can create a precarious situation that is at increased risk of infection. The surgeon should maintain a low threshold for soft tissue coverage with a gastrocnemius flap or free tissue transfer.

PATHOGENESIS

- This technique is applicable to bone loss from bone tumor excision, bone loss from trauma such as an open fracture, and osteomyelitis requiring debridement.

NATURAL HISTORY

- Management of bone defects around the knee are a challenging problem that frequently requires multidisciplinary management between general surgery, orthopedic surgery, plastic surgery, and infectious disease.
- Before instituting the described procedure, the surgeon must obtain a clean bone defect with viable tissue that is free of infection.
- This may require multiple surgeries focusing on debridement, antibiotic cement spacer placement, bone stabilization, soft tissue coverage, and intravenous antibiotics to prepare the area for the described definitive procedure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient presentation and reason for the bone defect influence the treatment approach and time interval to the definitive bone grafting procedure.
- Trauma and infectious etiologies often require serial debridement and temporary stabilization with definitive stabilization and soft tissue coverage performed once a clean tissue bed is achieved.
- The surgeon should assess the neurovascular status of the involved extremity. A functional limb is a candidate for limb salvage. A severely compromised limb may be better with an early amputation.

- When pursuing limb salvage, the stability of the collateral ligaments should be tested by applying a varus and valgus stress to a slightly flexed knee.
- The patient should be asked to extend the knee against gravity to test the competency of the extensor mechanism.
- Laboratory studies depend on patient specifics and can be used to assess nutritional status, blood count recovery after chemotherapy, and inflammatory markers to assess for infection or response to antibiotics.

IMAGING

- Radiographs are used to assess defect size and provide an estimate of how much bone graft will be needed (**FIG 1A**). Further, the surgeon can plan implant needs to provide sufficient stabilization of the involved bone.
- Computed tomography and magnetic resonance imaging (**FIG 1B,C**) provide a detailed assessment of cortical bone and offer a volumetric assessment of the defect.

FIG 1 • **A.** AP radiograph, **(B)** coronal T1 MRI, and **(C)** coronal T2 MRI of a primary bone tumor of the lateral proximal tibia.

SURGICAL MANAGEMENT

- In the setting of a large bone defect (≥ 6 cm), surgery is generally necessary to improve function and facilitate weight bearing. The described technique has been utilized for defects up to 2.5 cm.¹
- The treatment goal is to create a clean and viable tissue bed that is then filled with a cement spacer to maintain the defect space and induce formation of a biologically active, vascularized membrane (**FIG 2**).

- After 4 to 6 weeks, the cement spacer is removed, and the defect is optimized for placement of autogenous bone grafting to facilitate reconstitution of the defect.²
- The cement spacer provides structural support to the bone, offloads the implant bridging the defect, maintains the bone void, facilitates formation of the induced membrane, and can be a conduit for local antibiotic elution.
- Bone graft is obtained using a reamer-irrigator-aspirator (RIA) system (Synthes, Paoli, PA).
 - This is a single-pass, negative pressure reaming system for obtaining intramedullary nonstructural autogenous bone graft.
- Compared to the traditional iliac crest bone used for the harvest of autogenous bone graft, RIA obtains more graft volume (on average 60 cc from the femur and 40 cc from the tibia)^{3,4}, and the graft appears to have equivalent osteoconductivity and better osteogenicity and osteoinductivity.⁵⁻⁷ Studies also suggest a greater concentration of stem cells. Harvest of bone graft with RIA is also less invasive and associated with less donor site morbidity.⁸
- Use of RIA to obtain autogenous bone graft is indicated in skeletally mature patients with normal femur anatomy. Relative contraindications include metabolic bone disease, presence of metastatic bone cancer in the donor bone, active osteomyelitis in the donor bone, known bleeding disorder, and osteoporotic patients with thin cortices.⁵
- Bone graft volume can be extended with cancellous allograft and demineralized bone matrix. Extension is common, and when used, we add fresh bone marrow aspirate to provide osteogenic mesenchymal stem cells to the structural allograft.⁶
- The induced membrane is a vascularized soft tissue layer that forms around the cement spacer. It is composed of an outer layer of fibroblasts and collagen and a synovium-like inner layer. It is rich in growth factors and osteoinductive elements that include BMP-2. Upon placement of autogenous bone graft, the membrane prevents graft resorption and facilitates the formation of new cortical bone.⁸

FIG 2 • A. Intraoperative preparation of the bone defect. **B.** Fluoroscopic view of debridement with high-speed bur. **C,D.** Placement of an antibiotic spacer into a proximal tibia bone defect.

Preoperative Planning

- Bone reconstruction is a two-stage process.
- Bone defects from infection or trauma may require serial debridement with placement of a temporary cement spacer and temporary stabilization of the bone with an external fixator or long plate. The cement spacer is often loaded with antibiotics to provide a local elution.
- A clean defect can be judged by negative cultures, bleeding tissues, and maintained continuity of the defect with the intramedullary canals.
 - Once clean, the patient is eligible for stage 1 of this procedure.
- For infection, intravenous antibiotics are generally given for the 4 to 6 weeks that the cement spacer is implanted. These antibiotics are an adjuvant and do not make up for an inadequate debridement.⁹
- Patients are followed with serial inflammatory markers such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) to judge eradication of the infection.
 - At this point, the patient has a clean bone defect that is free of infection.
- The patient should be counseled on the risks of surgery, which include fracture of the donor bone, infection of the recipient site, and possible need for blood transfusion(s).
- Patients should know that there may be a need to surgically stabilize the donor femur due to bone perforation by the reamer head or perceived postoperative fracture risk based on the assessment of cortical thickness after RIA use.
- Patient should be aware of the donor site location and possible weight-bearing

restrictions after surgery. In general, we try to use a donor bone on the ipsilateral side of the bone defect in order to maintain one good lower extremity to aid postoperative rehabilitation.

FIG 3 • A,B. Preoperative radiographs of the donor femur. The inner diameter of the isthmus is used to determine the reamer head size needed for bone graft harvest.

- Preoperative radiographs are done of the donor femur (**FIG 3**). The surgeon assesses cortical thickness, inner cortical diameter at the isthmus, and length of the femur. This facilitates decision-making on appropriate indications for RIA use, estimation of reamer head size, and determination of the appropriate length of the RIA drive shaft (360 or 520 mm).
- The size of the reamer head is determined by measuring the isthmus of the donor long bone on both AP and lateral radiographs. A head size 1 to 1.5 mm larger than the smallest measured inner cortical diameter at the isthmus should be used. If this measurement is done intraoperatively with fluoroscopy, the surgeon should factor in the distance of the ruler from the actual bone. The real canal is larger than the measurement. In general, the canal is 1 mm larger when the ruler is 2.5 cm away from bone and 2 mm larger when the ruler is 5 cm away.
- To use RIA, a power driver with 3.5 to 4.5 Nm of torque and 700 to 900 rpm should be used. Drills with torque greater than 6 Nm are too powerful and should not be used.
- In the operating room, the surgeon will need a radiolucent table, large

fluoroscopy machine, 3-L bags of normal saline, a separate Mayo stand to hold the RIA, and a source of negative pressure suction.

- A tourniquet may be used at the bone defect site if brisk bleeding is present during preparation of the area. Attempts are made to avoid tourniquet use as it can compromise the assessment of tissue viability.
- The patient may benefit from a preoperative discussion with the anesthesia team regarding use of regional or neuraxial anesthesia. This can provide optimal intraoperative and postoperative pain control.

Positioning

- Patient position and draping frequently requires coordination between orthopedic surgery and plastic surgery.
- Position should facilitate debridement of the bone defect, harvest of bone graft, and any soft tissue coverage procedures. It may be necessary to change the patient's position during the surgery; a repeat sterile prep and drape is then performed.
- For bone defects about the knee, a supine position with a bump under the gluteus is often sufficient.
- A large C-arm should be placed opposite the side where bone graft will be harvested. The monitor is positioned at the end of the operating room table.

Approach

- RIA bone graft harvest from the femur is generally obtained through an antegrade approach through a greater trochanter start side. This requires an approximately 3- to 4-cm incision, approximately one hand breath above the top of the greater trochanter and 2 to 3 cm posterior to the midline axis of the greater trochanter.
- Medial and lateral/anterolateral approaches to the distal femur and proximal tibia for the bone defect are well described in surgical approach textbooks.

TECHNIQUES

- **Induced Membrane With Intramedullary Autogenous Bone Grafting With Bone Marrow**

Aspiration and Intramedullary Nailing

■ Stage 1

Cement Spacer Placement and Internal Fixation

- For tumors, the patient starts stage 1 at the time of surgical excision of the malignancy.
- Stage 1 simply consists of placing a block of cement into a clean bone defect. The cement is hand mixed in a bowl and allowed to reach a doughy consistency. The goal is to maintain the defect space while avoiding the interdigitation of cement into the bone, which would make removal difficult (**TECH FIG 1**).
- It is important to overlap the bone ends with cement to induce a pseudomembrane longer than the defect itself.
- In the absence of infection, definitive internal fixation can be placed at this time. When possible, we prefer a titanium intramedullary nail to maintain the canal, facilitate early weight bearing, and prevent future central necrosis of the autogenous bone graft.
- Intramedullary implants can be placed antegrade or retrograde in the femur and antegrade in the tibia. New implants allow for fixation in short bone segments.
- In defects close to the joint, a strong 4.5-mm periarticular plate with fixed-angle locking screws into the short segment is most often used.

TECH FIG 1 • Placement of cement spacer into defect

to generate an induced membrane.

- In the setting of infection, it is best to avoid metal implants altogether and rely on splints. Sometimes it is necessary to place antibiotic intramedullary nails or bridge plates coated in antibiotic cement for adequate bone stabilization.

Soft Tissue Coverage and Monitoring

- If soft tissue coverage is needed, it is done after placement of the cement block spacer. Defects in the proximal tibia are often augmented with a medial gastrocnemius flap (**TECH FIG 2**).
- If soft tissue coverage is not an urgent concern, muscle flap coverage can also be done at the time of definitive bone grafting.
- The patient is monitored for the next 4 to 6 weeks.
 - Weight bearing on the affected lower extremity is dictated by the strength of the cement/implant construct. At a minimum, the construct must provide enough stability to allow knee range of motion.
- Patients with infection have periodic checks of inflammatory markers.
 - At the end of intravenous antibiotics, these patients are followed for an additional 2 to 3 weeks off antibiotics to monitor for any signs of recurrent infection before proceeding with stage 2 of this procedure.

TECH FIG 2 • A,B. Medial gastrocnemius rotational flap of a proximal tibia bone defect.

■ Stage 2

Spacer Removal and Bone Preparation

- The second stage begins by accessing the bone defect through the prior surgical incision.
 - Patient positioning should allow access to the bone defect and the hip selected for RIA bone graft harvest.
- When exposing the bone defect site, it is very important to carefully incise the induced membrane longitudinally and use a Cobb or periosteal elevator to isolate the membrane off of the cement spacer.
- The spacer often needs to be fractured with an osteotome and removed piecemeal.

- Bone ends are gently debrided of any fibrous tissue, and if no intramedullary implant, the intramedullary canals are accessed with a flexible reamer or high-speed bur to assure continuity.
- With infection, the surgeon should maintain a high level of suspicion for persistent infection.
 - Intraoperative frozen section for high-powered fields can be done for an objective measure of continued infection.
 - In general, a finding of more than 5 to 10 WBC/HPF warrants consideration for irrigation and debridement with another 6-week cycle of cement spacer and intravenous antibiotics.
- When the bone defect site is clean with a nice induced membrane (**TECH FIG 3**), attention is turned to the intramedullary harvest of autogenous bone graft using RIA.

Inserting the Guidewire

- A large C-arm fluoroscopy positioned on the opposite side of the patient is used to localize the top of the greater trochanter.

TECH FIG 3 • Clean bone defect after removal of the cement spacer. The defect is contained by the induced membrane.

- A 3- to 4-cm incision is made approximately 5 cm proximal and 2 cm posterior to the midline of the greater trochanter.
- A 3.2-mm guide pin is positioned at the tip of the greater trochanter on AP fluoroscopy and in the midline of the greater trochanter on the lateral view. The guide pin should aim for the center of the intramedullary canal at the

level of the lesser trochanter (**TECH FIG 4**).

- Once the guide pin is driven 5 to 6 cm into the bone and the position confirmed on fluoroscopy, the skin and deep fascia are incised with a scalpel around the guide pin to cannulate the guide pin with a soft tissue protector.
- A 12-mm cannulated reamer is used through a soft tissue protector to drill 3 to 4 cm into the greater trochanter to create a start site.
- The power source should be set to “drill,” and the surgeon should allow the drill to spin at full speed before contacting greater trochanter bone. This will create a clean entry site.
- Limited entry into the bone will allow more bone to be harvested.

TECH FIG 4 • Illustration of the antegrade start site for RIA bone graft harvest. The guide pin is placed in-line with the center of the femoral canal.

- A 2.5 mm diameter, 950 mm in length, ball-tipped guidewire is placed through the greater trochanter start site and inserted down the intramedullary canal of the femur to roughly 2 to 3 cm above the physeal scar of the distal femur.
- AP and lateral fluoroscopy is undertaken to assure the guidewire is within

the intramedullary canal.

- A T-chuck handle may be placed onto the guidewire and gently tapped with a mallet to aid the guidewire passing through the metaphyseal bone of the proximal femur.
- A slight bend is often required in the distal aspect of the guidewire to direct the guidewire into a center-center position in the distal femur.
 - This helps avoid eccentric reaming and minimizes the risk of cortical perforation by the sharp reamer head.
- Measure the length of the guidewire within the femur to select the proper length of the RIA drive shaft. Length options are 360 and 520 mm.

Preparing the RIA

- The RIA system comes with a ruler that overlay the patient's skin (**TECH FIG 5A**).
 - With intraoperative fluoroscopy, the inner isthmic diameter of the femur in both AP and lateral planes can be measured to determine the size of the reamer head needed to obtain the necessary volume of bone graft.
 - The intramedullary canal is often elliptical, and one measure will be smaller than the other.
 - A reamer head that is 1 to 1.5 mm larger than the smallest isthmic diameter is recommended.
 - Reamer heads are available in 12 to 19 mm diameters.
- As noted earlier, measurement of the isthmus at the skin level by intraoperative fluoroscopy requires a correction for magnification. The actual size of the isthmus is larger than the measurement. This is important when selecting the size of the reamer head.
- On a separate Mayo stand, the RIA device is assembled according to manufacturer specifications (**TECH FIG 5B**).
 - The reamer head is front-end cutting and sharp. The surgeon should assure several things: that the reamer head is mated correctly with the drive shaft, that the rubber seal is placed over the proximal drive shaft before it is connected to the power source, and that the plastic casing protecting the rotating connection between the power source and the drive shaft is locked into place.
 - Connect irrigation to RIA, it is the most proximal, smaller port labeled "I."
 - Connect suction to RIA. It is the most distal, larger port labeled "A."
 - Attach the 100-cc filter to the suction ("A" port). This has a particulate

filter of 500 μ m to capture the viscous autogenous bone graft.

- Place the power source on the “drill” setting during reaming to allow for high speed and low torque.
- A 3-L bag of normal saline should be placed 3 ft. or higher above the RIA device to allow adequate gravity flow. The suction tubing should be attached to a closed, continuous suction canister with a large reservoir.

TECH FIG 5 • A. Intraoperative measurement of the femur isthmus using fluoroscopy. **B.** The reamer-irrigator-aspirator (RIA) device. The ports for fluid inflow and outflow are labeled. The aspiration port connects to a filter that captures the intramedullary bone graft.

Reaming the Graft Material

- Test the RIA device on the Mayo stand outside of the patient by starting the irrigation and suction. Activate the power source to assure the reamer tip is properly revolving.
- The RIA system is single pass and continuously irrigates and suctions within the intramedullary canal. This decreases intramedullary temperatures and decreases viscosity of the graft.
- Place the RIA system over the guidewire. Before entering the patient, verify flow of irrigation. Insert the device through the soft tissue protection sleeve and turn on suction when the reamer head is set into the insertion site at the greater trochanter.
- Before starting, warn anesthesia about possible blood loss due to the negative pressure suction.
- The power source should be fully activated.
- RIA is propagated through an advance-withdraw technique every 2 to 3 cm

to avoid clogging of the aspiration tubing by particulate graft (**TECH FIG 6A**).

- The surgeon should move slowly through the isthmus to allow time for appropriate emulsification of the graft (**TECH FIG 6B**). It is important not to forcibly push through resistance as incarceration of the reamer head or clogging of the aspiration tubing may occur.
- Fluoroscopy should be used liberally during active reaming to monitor the position of the reamer head.
 - The surgeon should continually assess for eccentric reaming, which most commonly takes place in the medial proximal femur and distal anterior femur.
 - It bears repeating that the surgeon must take great care to avoid incarceration of the reamer head at the isthmus and perforation of the anterior cortex as well as the knee joint distally.
- When reaming distally in the femur, a lateral fluoroscopic view is recommended to assess for perforation of the anterior femoral cortex.
- Aspiration tubing should be periodically checked to assure flow of bone graft and to assure the line is not clogged.
- When actively reaming, both irrigation and suction should be turned on. When reaming is paused, both lines should be stopped to avoid excessive blood loss.
- To obtain more graft volume, the surgeon can rotate the guidewire to capture the metaphyseal bone in the medial and lateral aspects of the distal femur.
- The RIA system should continue to be fully activated while withdrawing the drive shaft from the femur. If this is difficult, the surgeon can reverse the direction of the reamer head to facilitate removal.

TECH FIG 6 • A. Use of intraoperative fluoroscopy to follow the reamer head during RIA bone graft harvest. It is important to assure that the sharp reamer head remains central in the intramedullary canal. **B.** Appearance of RIA autogenous bone graft after harvest.

Completion of Reaming

- When the reamer tip is back at the top of the greater trochanter, turn off suction and irrigation. The device is removed.
- Pack the proximal femur skin incision with gauze or a hemostatic agent.
- View the collection canister, which has markings on the outside to estimate the volume of graft obtained.
- If more graft is needed, upsize the reamer head by 0.5 to 1 mm and perform another pass down the femur. Generally, one to two passes are sufficient.
- Once graft volume is adequate, disconnect the collection canister, and move it over the sterile operating room table.
- Remove the lid, and use a plunger to compress the graft.
- Invert the filter with the plunger in place to remove the inner filter. Turn the inner filter vertical, and use the plunger to remove the graft into a sterile basin.

Harvesting Bone Marrow

- Fresh bone marrow is then obtained by palpating the medius pillar of the ilium.
- Thumb pressure can be used to push soft tissues toward the abdomen to feel the thickness of the pillar.
- A small skin puncture with a no. 11 blade scalpel is made over the medius pillar.
- A disposable 14-gauge T-handle bone marrow biopsy needle is introduced. Tactile feel is used to center over the medius pillar bone (**TECH FIG 7**).
- Gentle, sustained pressure is applied with a back and forth rotation to puncture the bone and gain access to the marrow space between the inner and outer shelves of the ilium. The needle is generally inserted around 3 cm.
- The top of the T-handle is rotated 90 degrees to remove the stylet. A 12- or

20-mL syringe is engaged to the Luer-lock to aspirate bone marrow. The amount of bone marrow needed is proportional to the size of the defect. The goal is to saturate the final volume of bone graft.

- The syringe of bone marrow aspirate is disconnected, and the needle is withdrawn. Pressure is applied to the puncture site for 5 to 10 minutes, and a Steri-Strip is placed over the puncture site.

Graft Placement

- The autogenous intramedullary bone graft and bone marrow aspirate are mixed together in a sterile basin.
- The graft is extended with 1- to 4-mm cancellous allograft and demineralized bone matrix to create an appropriate graft consistency and to achieve adequate volume. The goal consistency is equivalent to gritty toothpaste.
- The recipient bone defect undergoes a final low-pressure irrigation.
- The bone graft mixture is packed into the defect with thumb pressure. Avoid dense packing of the graft with instruments such as a bone tamp.
 - Highly compacted graft does not incorporate as well (**TECH FIG 8A–D**).
- Suture the induced membrane closed (Video 1). This should completely cover the graft as it prevents resorption and promotes the formation of the cortical bone.

Video p7-c031

- All surgical sites should be closed in layers. Suture for skin closure is at the discretion of the surgeon (**TECH FIG 8E**).

- Sterile dressings are applied.

TECH FIG 7 • A. Bone marrow biopsy needle insertion site in the medius pillar of the pelvis. **B.** The needle is gently twisted back and forth as it is inserted.

TECH FIG 8 • A,B. The bone defect is filled with bone graft with fresh bone marrow aspirate. The graft completely fills the defect, but impaction of the graft is

avoided. In a different patient, **(C)** intraoperative AP and **(D)** lateral fluoroscopic views of the proximal tibia filled with autogenous bone graft and stabilized with a lateral plate. **E.** Skin closure after RIA bone grafting and stabilization into a defect with an induced membrane.

PEARLS AND PITFALLS

Bone graft harvest

- Try to harvest RIA from the femur ipsilateral to the bone defect. This maintains an unaffected lower extremity to facilitate postoperative rehabilitation.
- While using RIA, keep the filter for the bone graft in a vertical position to avoid over washing and loss of growth factors.
- When finished with RIA, disconnect the irrigation and aspiration tubing to avoid unsterile tubing coming up to the sterile field and causing contamination.

Union

- Central graft often remains avascular; the use of a nail or resorbable mesh to maintain the native intramedullary canal helps limit graft volume and improves the formation of cortical bone⁸.
- Bone stabilization with an intramedullary implant is preferred as this preserves the native medullary canal and helps to prevent the lack of incorporation seen in central graft in larger bone defects⁸. This is not always possible, however, and plate fixation may be necessary based on the defect itself (**FIG 4**).

Fracture

- Consider restricted weight bearing or placement of a prophylactic intramedullary nail after RIA use. Especially if the donor bone has narrow cortices or the patient is osteopenic or osteoporotic.³
- Consider use of iliac crest bone grafting in osteoporotic patients.
- Fluoroscopy in orthogonal planes is useful to assure a proper start site for RIA harvest and to assess cortical thickness of the femur after RIA use.
- A greater trochanter start site for RIA harvest minimizes the reamer entry angle and decreases the risk of postoperative femoral neck fracture.

	■ Reaming ≥ 2 mm of the inner diameter of the femoral isthmus decreases the torsional strength of the femur. ■ It is important to place the guidewire for RIA bone graft harvest in the center of the intramedullary canal to avoid eccentric reaming of the femoral cortex.
Blood loss	■ RIA suction can lead to rapid blood loss. It is important to communicate this to anesthesia. ■ Patients should be typed and crossed before starting the procedure. ■ Stop RIA suction when not actively reaming.⁵ ■ Pack the hip incision at the conclusion of RIA use to avoid a gluteal hematoma.
RIA irrigation water	■ Filtrate water contains viable cells including mesenchymal stem cells.¹⁰ ■ Adding filtrate to the harvested bone graft may improve incorporation and corticalization.

POSTOPERATIVE CARE

- Weight-bearing restrictions for the bone defect are advised. The length of time depends on the size of the bone defect, implant use, graft harvest technique, and patient bone stock. Implementation is at the discretion of the surgeon and is determined on a case-by-case basis.
- Restrictions for the bone graft harvest site are generally advised if multiple RIA passes are performed or thin femoral cortices are noted at the end of the procedure.
- A knee immobilizer is often used for 2 weeks to facilitate soft tissue healing. Physical therapy is then started to work on knee joint range of motion.
- First radiographs are done 6 weeks from surgery (**FIG 5**). Serial radiographs are used to assess the incorporation of bone graft.
- Bone defects stabilized with an intramedullary implant can often start partial progressive weight bearing at 3 to 4 months after surgery.
- Computed tomography can be used to further investigate bone graft incorporation and determine the necessity of additional bone grafting procedures.

FIG 4 • Fluoroscopic image showing stabilization of a proximal femur bone defect with a 4.5-mm periarticular plate. The small amount of residual bone at the joint level did not allow for an intramedullary implant.

OUTCOMES

- Union of a bone defect after autogenous bone grafting appears to be independent of defect length.¹¹ Defects up to 25 cm have been addressed with this technique (Norris).
- Radiographic healing is often seen by 4 months.
- Approximately 70% of defects heal by 6 months and 80% heal by 1 year.¹

FIG 5 • **A.** AP and **(B)** lateral radiographs of the bone defect after definitive bone grafting with autogenous, intramedullary bone graft with graft extension and fresh

bone marrow aspirate.

- Approximately 50% of patients heal with just one bone grafting procedure, 35% heal with more than one bone grafting procedure (McCall).
- Long-term donor site morbidity is less with RIA harvest compared to iliac crest bone graft harvest.^{4,12}

COMPLICATIONS

- The complication rate with RIA harvest is 1.96% to 6.2%.^{3,4}
- Iatrogenic fracture of the femur from RIA harvest is the most common complication, and it is related to technical aspects of the procedure including poor start site, eccentric reaming, and over-reaming.
- After RIA harvest, the femur is weakest in torsion.
- Femoral shaft fracture, femoral neck fracture, and anterior cortical perforation of the femur are described complications with RIA harvest.
- Heterotopic ossification of the abductors can be seen at the RIA start site and is generally asymptomatic.
- Problems encountered at the bone defect site include deep infection, nonunion, and implant loosening/failure.
- Nonunion rate is approximately 15%; causative factors include inadequate graft volume, suboptimal graft placement, and infection.⁸

Soft Tissue Coverage of the

Knee: Gastrocnemius

Muscle Flap

32

CHAPTER

Hani Sbitany

DEFINITION

- Soft tissue defects around the knee, or the anterior third of the tibia, often cannot be treated with local fasciocutaneous flaps; instead, the most reliable local/regional coverage option is the rotational gastrocnemius muscle flap.¹
- This is taken as a pure muscle flap, and in defects that include skin loss, the muscle is immediately skin grafted.
- This rotational muscle flap is well perfused, given its axial blood supply, and provides excellent soft tissue coverage and reliable reconstruction of defects involving the underlying bone, tendon, or exposed surgical hardware.²

ANATOMY

- The gastrocnemius is a bipennate muscle, located in the superficial posterior compartment of the lower extremity.
 - Other muscles in this compartment include the soleus muscle and plantaris muscle.
 - These muscles come together, via their common insertion in the posterior surface of the calcaneus, to create the Achilles tendon.
 - These muscles act to cause flexion of the ankle, when the knee is extended.
- The gastrocnemius muscle is the most superficial of these muscles, situated just deep to the posterior calf skin and subcutaneous tissue, and consists of a medial and lateral muscle head.
- The blood supply to these gastrocnemius muscles comes from the sural artery and vein, which are direct branches from the popliteal vessels; the motor nerve innervation derives from the tibial nerve.

- The medial and lateral heads of the gastrocnemius muscles can be separated from each other at their midline confluence, and each muscle belly can be isolated on its medial or lateral sural vessel pedicle, respectively.
- The medial head of the gastrocnemius muscle is usually longer and wider than the lateral head and thus has a greater arc of rotation and reach as a rotational flap; for this reason, the medial head is most commonly harvested for proximal lower extremity reconstruction.³
- Because the Achilles tendon is made up of contribution from all four muscles in the superficial posterior compartment, the ankle can still safely flex following harvest of one belly of the gastrocnemius muscle.

PATHOGENESIS

- As stated, the gastrocnemius rotational muscle flap is most commonly used for soft tissue reconstruction of defects situation around the knee or the proximal third of the tibia.
- There are many possible causes of defects in this region:
 - Traumatic wounds
 - Oncologic resection wounds
 - Soft tissue infection/necrotizing fasciitis
 - Burn, or burn contracture release, wounds
 - Breakdown of surgical wound after total knee arthroplasty
 - These wounds often contain exposed surgical hardware.
 - Breakdown of wound following patella or patellar tendon repair

PATIENT HISTORY AND PHYSICAL FINDINGS

- The cause and chronicity of the soft tissue wound in this area must be carefully defined.
- The patient must be questioned for a history of prior lower extremity surgery or injury along the entire limb that may have altered soft tissue anatomy or neurovascular supply.
- The specific wound location and size must be recorded and examined carefully to ensure that a rotational gastrocnemius muscle flap will adequately reach this wound with minimal tension.⁴
 - With the patient contracting the calf muscles, and flexing the ankle, the distal portion of the gastrocnemius muscle belly can be visualized or palpated, and this is the point that should be used in assessing muscle flap reach.
 - If this is not the case, then free tissue transfer must be considered.

- Physical examination of the knee and ankle must be performed, with range of motion being carefully assessed.
- Range of motion at the knee (normal 135 degrees) must be defined, along with confirmation of normal flexion in all positions.
- Range of motion at the ankle (normal 70 degrees) must be defined, along with normal flexion with the knee extended.
- If exam reveals normal findings, then rotational medial or lateral gastrocnemius muscle flap is safe.

IMAGING

- Routine imaging of the lower extremity is not necessary prior to gastrocnemius rotational muscle flap.
- If the patient has a history of peripheral vascular disease, a preoperative angiogram or CT angiogram can be obtained, to assess patency of popliteal and sural arteries.
- If the patient has a history of deep vein thrombosis, or venous insufficiency, then lower extremity venogram can be performed.

SURGICAL MANAGEMENT

Preoperative Planning

- Once the gastrocnemius muscle flap has been chosen as the reconstructive option, the surgeon must determine location of the muscle flap donor incision.
- In most cases, for knee defects (anterior, lateral, or medial knee), the muscle harvest incision is separate from the wound being reconstructed, and the muscle is tunneled underneath the intervening skin bridge.
- For wounds over the proximal third of the anterior tibia, it is common to extend the harvest incision from the defect, so that they are in continuity.

Positioning

- The patient is most commonly placed in a supine position on the operative table.
- In some cases, based on wound location and dimensions, it is easier to harvest with the patient in a lateral decubitus position, and this is also acceptable.
- When the patient is supine, the entire lower extremity should be circumferentially prepped into the operative field, such that the leg can be

moved and manipulated during surgery.

- This allows for placement of the leg in a “frog-leg” position, with the knee flexed and turned out, and the foot brought in such that its plantar surface is against the contralateral lower extremity.
- This allows for easier harvest of the medial gastrocnemius muscle.
- It is also advisable to again check the arc of rotation and the reach of the gastrocnemius muscle, relative to the wound, to ensure successful soft tissue coverage, once the patient is positioned on the table.

Approach

- The incision is planned as a longitudinal incision of 10 to 15 cm length.
 - For the medial or lateral gastrocnemius muscle flap, the anterior border of the muscle is palpated through the skin and marked along its entire length.
 - The incision can be planned along this same longitudinal direction, usually one or two finger breadths posterior to this point, such that the muscle will be directly underneath the entire length of the incision, but it is still anterior enough that the harvest can easily proceed with the patient supine, and the legs in the “frog-leg” orientation.
- This incision location and length are adequate for the following necessary sites of surgical exposure:
 - Proximal exposure of the popliteal region and the sural vessel pedicle
 - Posterior exposure of the confluence between the medial and lateral gastrocnemius muscles
 - Distal exposure of the Achilles tendon
- The entire incision is made for muscle flap harvest, and dissection proceeds down through the skin, subcutaneous tissue, and superficial fascia, to enter the superficial posterior compartment of the leg.
- During this portion of dissection, when harvesting the medial gastrocnemius muscle, the saphenous vein should be identified and preserved.

TECHNIQUES

■ Elevation of the Gastrocnemius Muscle Flap

- The entire incision is made for muscle flap harvest, and dissection proceeds

down through the skin, subcutaneous tissue, and superficial fascia, to enter the superficial posterior compartment of the leg.

- During this portion of dissection, when harvesting the medial gastrocnemius muscle, the saphenous vein should be identified and preserved. Once the posterior compartment is entered, the gastrocnemius muscle is immediately encountered along its posterior/superficial surface.
- The entire muscle belly should then be free from the entire deep surface of the posterior fascia overlying it (**TECH FIG 1A**).
 - This should be a relatively hemostatic dissection that can be done sharply or bluntly, as this plane between gastrocnemius muscle and overlying fascia is largely avascular loose areolar tissue.
- Once this has been done, the free border of the muscle, either medial or lateral, should then be identified along its entire length and used as the access point to dissect the deep surface of the muscle belly (**TECH FIG 1B**).
 - This space is entered, and the gastrocnemius muscle is dissected free from the underlying, deeper soleus muscle.
 - In this plane, the plantaris muscle and tendon (long and thin) will be encountered and should also be preserved (if present).
 - This deep dissection can be performed along the entire longitudinal length of the muscle, distally to the point of the Achilles tendon.
 - This dissection can stop at the point of confluence of the medial and lateral gastrocnemius muscles, along their deep surface, as only the half of the muscle being dissected will be elevated as a flap.
- At this point, surgical dissection should have fully freed up the deep and superficial/posterior surfaces of the gastrocnemius muscle belly (**TECH FIG 1C**).
- Next, the muscle will be elevated in a distal to proximal direction, moving up the leg.
- First, the muscle belly to be elevated is horizontally detached above the start of the Achilles tendon.
 - It is critical that the Achilles tendon not be disturbed and the entire fascial contribution of the gastrocnemius muscle within the Achilles tendon remains intact.
 - Thus, the muscle is transected one fingerbreadth above the point where the tendons of all the muscles in this compartment join to form the Achilles.
 - At this point, the gastrocnemius muscle will contain some tendon, and this

can be used for suture anchoring on inset of the muscle flap in the defect.

- Next, the half of the gastrocnemius muscle being elevated then is lifted in a distal to proximal direction, by separating the medial and lateral gastrocnemius muscles from each other (the last remaining point of attachment).
 - This area must be carefully identified along its entire length based on changing directionality of muscle fibers (**TECH FIG 1D**).
 - Often times, this point between the medial and lateral heads of the gastrocnemius muscles is not a distinct plane, and thus, separation should be performed with electrocautery to minimize bleeding.
 - Numerous minor perforators exist between the medial and lateral heads of the muscle, and these must be ligated.
- This elevation of the muscle in the proximal direction, by separating the two halves of the gastrocnemius, should be performed just beyond the point at which the freed muscle can rotate into the defect with no tension or stretch (**TECH FIG 1E**).
 - Often times, the dissection can stop well before the point where the sural vessels enter the deep surface of the muscle, as elevation to this point is not necessary for adequate rotation.⁵
 - In such cases, the sural vessels are never directly visualized, and this will reduce risk of vascular pedicle injury.
 - However, if necessary for adequate muscle rotation, dissection can proceed to this point, and the sural vessels can be identified, dissected free, and preserved.
 - In some cases, due to the need for excessive rotation, the muscle origin on the femoral condyle can be identified and transected.
 - This will result in a significant increase in muscle rotation and length of transposition.
 - Without the stability of the muscle insertion to prevent excess stretch on the sural vessels, they must be carefully watched during rotation and inset, to avoid excess tension and possible vascular traction injury or avulsion.
- Once the muscle has been fully dissected and elevated, it can then be rotated into the soft tissue defect (**TECH FIG 1F**).
 - If the muscle is tunneled underneath a planned skin bridge, it must be ensured that the skin bridge is not excessively tight or compressive on the underlying muscle flap.

- The muscle is usually inset with the previous posterior/superficial surface of the muscle belly externalized in the wound, as this portion of the muscle does not contain aponeurosis or fascia and thus accepts a skin graft well.
- The muscle is then inset into the soft tissue defects and secured circumferentially to the lower extremity skin and subcutaneous tissue with sutures (**TECH FIG 1G**).
- The proximal portion of the muscle, in the area of the sural vessels, should then be again examined after inset, to ensure no tension or stretch on this area.
- Finally, a skin graft can be placed on the superficial surface of the muscle flap at this point.
- The donor site can then be closed primarily over a drain, at the fascia and skin level.

TECH FIG 1 • A. Patient with a medial knee soft tissue wound, adequately debrided, and ready for soft tissue reconstruction. Planned medial gastrocnemius muscle flap is exposed through longitudinal incision shown. Posterior leg skin, subcutaneous tissue, and fascia have been elevated off the superficial surface of the

muscle flap. **B.** Dissection of the deep surface of the gastrocnemius muscle flap from the underlying soleus muscle. The aponeurosis of the soleus muscle is visible deep to the gastrocnemius muscle. The plantaris tendon is visible distally in the donor site and runs along the border of the gastrocnemius muscle. **C.** Both the deep and superficial surfaces of the medial head of the gastrocnemius muscle have been fully dissected, and the muscle has more freedom of movement. **D.** The longitudinal midline border between the medial and lateral heads of the gastrocnemius muscle is visible, by its overlying streak of fat. This will be the point of separation of the two muscle bellies. **E.** Following transection of the medial gastrocnemius muscle proximal to the Achilles tendon, and separation of the medial and lateral bellies of the muscle in the midline, the medial gastrocnemius muscle flap has now been elevated. The vascularized soft tissue bulk (width and thickness) afforded by this flap is clearly visualized. **F.** The muscle flap passed under the skin bridge and into the soft tissue wound. The size and reach of the muscle provide adequate coverage for the wound. **G.** The medial gastrocnemius muscle flap, following complete inset into the wound. The muscle is well perfused, with no pressure or tension. At this point, the muscle belly can be skin grafted, and the donor site can be fully closed in primary fashion.

PEARLS AND PITFALLS

Muscle flap elevation	■ The muscle flap only needs to be dissected proximally to the point where it can safely be rotated and inset into the wound, without tension; often times, complete elevation proximally to the sural vessel level is unnecessary and to avoid risk of vascular disruption.
Tunneling	■ The tunnel or skin bridge that the muscle flap passes under must be relaxed and without underlying tightness, to avoid muscle flap congestion and flap loss; if necessary, the fascia on the underside of the tunnel skin can be incised to increase the size of the tunnel.
Long muscle transposition length	■ In cases where the muscle flap must be advanced a long distance, it can be detached from the femoral condyle, to allow for a significant increase in reach; in these cases, the sural vessels must be continuously examined for a relaxed state without stretch, as they are no longer stabilized by the proximal muscle insertion.
Hemostasis	■ Hemostasis is critical, in both the muscle donor site, and in the wound being reconstructed, as tension from a hematoma can occlude the venous outflow and result in muscle flap loss.

POSTOPERATIVE CARE

- Postoperatively, the lower extremity is placed in a stabilizing knee immobilizer.
- This reduces muscle stretch or tension in the acute healing phase and reduces muscle flap edema.
- During this period, the patient may be kept nonweight bearing if deemed necessary or may be placed on limited foot pressure on the effected extremity while ambulating with crutches.
- Immobilization is usually kept on for 2 weeks, at which point the patient can begin knee flexion and normal ambulation (**FIG 1**).
- The skin graft can be covered for 5 to 7 days with either negative pressure therapy or with a bolster dressing.

COMPLICATIONS

- Hematoma

FIG 1 • Healed medial gastrocnemius muscle flap and overlying split thickness skin graft, 3 months after coverage operation in **TECH FIG 1**. Patient has stable soft tissue coverage and is ambulating without difficulty.

- Bleeding in either the donor site or the wound bed underneath the muscle flap must be treated immediately with hematoma evacuation, to avoid pressure on vascular pedicle and resultant muscle flap loss.
- Infection
 - Proper wound bed debridement and removal of all nonviable tissue prior to muscle flap coverage will reduce this risk.
 - When infection occurs, re-elevation of the muscle flap and aggressive washout should be performed.
- Flap loss
 - With complete flap loss, a secondary free flap often must be performed for wound coverage.
- Venous congestion
 - The entire flap must be elevated, and if congestion resolves, this usually indicates pressure or kinking on vascular pedicle, which must be resolved.
 - The tunnel must be checked for excessive tightness, and if this is the case, it can be opened with an incision and the muscle externalized in this area.

33 Soft Tissue Coverage of the Knee: Free Flaps

CHAPTER

Goo-Hyun Mun and So Young Kim

DEFINITION

- Although most soft tissue and bony defects around the knee are usually covered with locoregional tissues, free flaps should be considered when the desired donor territory is damaged or unsuitable or if the defect is extensive or complex. Free flaps offer benefits such as shortened recovery time, plentiful availability of donor tissue, and greater flexibility in flap design.¹
- Soft tissue defects of the knee can significantly influence gait; therefore, reconstruction should be done with proper planning and technique at an early onset.²
- Restoration of the thin and pliable skin for satisfactory appearance and function of the knee is an important reconstruction goal.

ANATOMY

- Popliteal vessels and vessels from the anterior knee can be recipients of microvascular free flap transfer for soft tissue coverage of knee defects.
- Recipient vessels for free flap.
 - Popliteal vessel and its branches (**FIG 1A**). The popliteal artery ranges from a proximal portion starting at the opening of the adductor canal to the distal portion lying behind the upper part of the tibia and fibula. The popliteal vessel and branches, including the superior medial and lateral genicular vessels (**FIG 1B**), medial and lateral sural vessels (**FIG 1C**), middle genicular vessels, and inferior genicular vessels, are considered the choice of recipient vessels for a free flap in the knee region. However, the approach to the popliteal vessels can be difficult when the anterior surface of the knee is reconstructed, and sural vessels are difficult to use in a free tissue flap to the region proximal to

the knee.³ Furthermore, there is a risk of increased complications caused by compression and twisting of the flap blood vessels, depending upon the postsurgical position of the patient.

■ Anterior knee (**FIG 2A**):

- Three vessels, including the descending genicular vessel and its branches (**FIG 2B,C**), and the descending branches of the lateral circumflex femoral vessels (**FIG 2D**) and anterior tibial vessels are considered the choice of recipient vessels for a free tissue transfer for the anterior knee region.
 - These recipient candidates have several benefits with supine positioning and easy accessibility to the recipient vessel. However, these branches may be very small vessels and, if so, may be of limited value and less reliable.³
- The perforators along the intermuscular septum of the upper leg and lower thigh can be used as recipient vessels for free flap reconstruction of the knee, but also note that these vessels may be small.⁴

FIG 1 • A. Muscular boundaries and branches of the popliteal artery and deep neurovascular structures in the posterior knee. **B.** Superior lateral genicular vessel for recipient vessel. **C.** Medial sural vessel for recipient vessel.

FIG 2 • A. Anatomy of recipient vessels of anterior knee region. **B.** Descending genicular vessels—vessel for recipient vessel. **C.** Descending genicular vessel—muscular branch to the vastus medialis for recipient vessel. **D.** Descending branch of the lateral circumflex femoral vessel for recipient vessel.

PATHOGENESIS

- Multiple prior operations and revision arthroplasties with atrophy/scarring of soft tissues
- Prior coverage of a total knee prosthesis and wound dehiscence due to infection
- Large post-traumatic defects
- Extensive soft tissue tumor excision
- Soft tissue necrosis and chronic infection after extremity radiation
- Necrotizing fasciitis and septic arthritis
- Burn scar contracture and post-traumatic stiff knee

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient history should focus on the exact mechanism and etiology of the defect.
- It is important to assess the medical history including vascular disease, systemic disease, and hypercoagulable state, which can influence the outcome of a microsurgical procedure.
- The preoperative evaluation for patients with a knee defect includes a detailed assessment of function limitations. The range of motion is a widely used measure of the knee joint, with a normal range of flexion of 45 to 105 degrees during routine activities and full extension to 0 degree.⁵

IMAGING

- The authors routinely perform preoperative computed tomography (CT) angiography of the lower extremity unless contraindicated to evaluate the regional vascular anatomy.
- Magnetic resonance imaging (MRI) can also be performed for evaluation of complex defects of soft tissue.

SURGICAL MANAGEMENT

- The proper selection of recipient vessels is essential for the success of a free flap and is arguably the most important factor that can affect the outcome.^{4,6} Major considerations regarding the choice of appropriate recipient site for revascularizing the flap include performing the microanastomosis outside the zone of injury and avoiding the need for vein grafts.⁷
- Extending the incision from the defect is used when there is a suitable adjacent recipient; however, a separate incision with subcutaneous tunneling can be effective for a distant recipient vessel approach.
- Options of free flap:
 - Commonly chosen flaps for soft tissue reconstruction of knee defects are an anterolateral thigh (ALT) flap, rectus abdominis muscle flap, deep inferior epigastric artery perforator (DIEP) flap, tensor fascia lata flap, superficial circumflex iliac artery perforator (SCIP) flap, latissimus dorsi musculocutaneous flap, and thoracodorsal artery perforator (TDAP) flap. The TDAP flap is favored by the authors because of several advantages including generous dimensions of the back, tissue thinness, relatively well-hidden donor scar, a long vascular pedicle, and the versatility offered by composite tissue transfer.

- When complex knee trauma accompanies a patellar tendon defect, the patellar tendon is traditionally restored using an autogenous graft, such as the semitendinosus tendon, gracilis tendon, and fascia lata, or an allograft. Because of the problem of delayed healing, fascia lata failure, and infection, a composite ALT myocutaneous flap with vascularized fascia lata can be utilized for one-stage reconstruction of complex knee defects.⁸
- When there is post-traumatic loss of the quadriceps femoris muscles with subsequent loss of knee extension, free functional transfer of the latissimus dorsi muscle⁹ and contralateral rectus femoris muscle¹⁰ can be utilized to restore knee extension.
- For stump coverage in above or below knee amputations, the distal placement of a flap to cover the entire weight-bearing surface of the stump is required.¹¹

TECHNIQUES

■ Wound Preparation

- The first goal of wound preparation is to debride all contaminated soft tissue or excise pathologic or necrotic lesions and to evaluate the extent of soft tissue defects in terms of size and components, including the bone, tendon, muscle, fascia, and skin (**TECH FIG 1**).
- A tourniquet is usually applied on the thigh during wound preparation.

TECH FIG 1 • Wound preparation of posterior knee defect after tumor extirpation.

■ Recipient Vessel Preparation

- Approach to the medial sural artery
 - The procedure can be performed with the patient in prone or semilateral decubitus position, with the recipient extremity down and the opposite leg crossed anteriorly, with simultaneous access to the contralateral back as a donor site (**TECH FIG 2A**).
 - Arising from the posterior aspect of the popliteal vessel, the medial sural vessel enters the deep surface of the medial gastrocnemius muscle. Between the muscular head of the medial and lateral gastrocnemius, the medial sural vessel is easily approached¹² (**TECH FIG 2B**). A branch of the tibial nerve usually accompanies the dominant vascular pedicle to the gastrocnemius muscle and should be preserved.⁷
- Approach to the descending genicular artery and its branches
 - The procedure is performed with the patient in the supine position, with the knee flexed and the thigh rotated externally.
 - The descending genicular vessel is divided into three equal branches:
 - A muscular branch to the vastus medialis muscle
 - A terminal articular branch supplying the periosteum of the medial condyle
 - A saphenous (superficial) branch
 - After medial retraction of the sartorius muscle, the descending genicular vessel can be identified immediately posterior to the vastus medialis muscle⁴ (**FIG 2B**). The intramuscular portion of muscular branch to the vastus medialis can be a candidate recipient vessel and is exposed through retrograde intramuscular dissection of a perforator overlying the vastus medialis⁴ (**FIG 2C**).
- Approach to the descending branch of the lateral circumflex femoral artery (LCFA)

TECH FIG 2 • A. Lateral decubitus position with the recipient extremity down and the opposite leg scissored anteriorly for the approach to the medial sural artery. **B.** The medial sural vessel is prepared for the recipient vessel.

- The procedure can be performed in the supine position.
- The descending branch of the LCFA with adequate size as a recipient vessel can be found in an area 10 to 15 cm above the upper margin of the patella; therefore, a donor flap must have a long enough pedicle.² After separating the rectus femoris medially from the intermuscular septum between the vastus lateralis and the rectus femoris, the descending branch of the LCFA is exposed. It travels with the muscular branch of the femoral nerve along the anterior border of the vastus lateralis toward the knee joint (**FIG 2D**).
- Approach to the superior medial and lateral genicular artery
 - The superior genicular vessels arise on either side of the popliteal fossa and

wind around the femur immediately above its condyles to the front of the knee joint.⁴

- In cases of a defect in the posterior knee, the superior medial genicular vessel is exposed after gentle retraction of the semimembranosus muscle at the level of the upper edge of the femoral condyle when the popliteal artery is in sight.³
- The superior lateral genicular vessel is identified above the lateral condyle of the femur as it courses laterally beneath the short head of the biceps femoris and the vastus lateralis¹³ (**FIG 1B**).
- Selection of recipient vein
 - Because the use of an accompanying concomitant vein as the recipient has the benefit of straightforward inseting of the flap, the deep vein system is usually considered the first choice of a recipient vein for a free flap in the lower extremity.
 - However, in this anatomical area of the knee, a superficial vein such as the great saphenous vein passing medial to the medial femoral condyle is sometimes in a more convenient position and is a better size match for anastomosis than the deep vein system.¹⁴

■ Assessment of the Defect

- Because the knee is a large diarthrodial (synovial) joint with an extensive range of motion, free flaps in this region should provide ample skin coverage to allow unrestricted joint mobility in flexion and extension and to facilitate ambulation.^{1,15}
- Final defect size and shape are exactly measured by making a transparent plastic or paper template that will be used for flap design. With the consideration both of minimizing restricted mobility of joint and avoiding redundancy of reconstructed flap, the measurement of anterior defect is usually conducted in slightly flexed knee status, and measurement of posterior defect is done in position of knee extension status.
- Dead space to be filled is also measured and accounted for in flap design/harvest.

■ Flap Harvest

- Outlines of the relevant muscle and other landmarks are drawn (**TECH FIG 3A**).
- Perforators are located using a handheld pencil Doppler, and the flap is designed using a template of the final defect.
- The targeted perforator(s) are identified by suprafascial dissection through a limited incision because the design of skin paddle could be potentially adjusted to capture the perforator securely within the flap, and then the whole skin paddle is elevated.
- Meticulous intramuscular dissection of the pedicle under loupe magnification with bipolar forceps is performed.
- A muscle chimeric perforator flap can be harvested as needed to fill dead space or to cover the artificial implant (**TECH FIG 3B**).
- Motor nerve branches to the muscle are maximally preserved during a perforator flap harvest, and the pedicle is divided when sufficient length is obtained.
- A closed suction drain is placed and the donor wound is primarily closed in layers (**TECH FIG 3C**).

TECH FIG 3 • A. Outline of the relevant muscle and landmarks are drawn on the donor site for flap design. **B.** Harvested muscle chimeric TDAP flap. **C.** Donor site that was primarily closed after flap harvest.

■ Microanastomosis with Temporary Inset

- Temporary inset of the flap is performed with a skin stapler.
- The vascular pedicle is comfortably laid to reach the recipient vessel without kinking, twisting, or tension. This is best accomplished by prudent preoperative planning and harvesting sufficient pedicle length.
- Wide exposure of the operative field and creation of a comfortable milieu are critical for successful microvascular anastomosis.
- Either end-to-end or end-to-side microanastomoses are performed and may depend on the size of the vessels.
- Vascular clamps are removed after completion of anastomoses. Warm saline is applied to the vessels and covered with moist gauzes for several minutes.
- After checking for patent arterial inflow and venous outflow, then perform careful hemostasis to evaluate for any bleeding points from the vascular pedicle or recipient vessels.

■ Final Inset

- Insetting of the flap is straightforward because it should have been harvested based on an exact template of the defect.
- The muscle component of a chimeric flap is placed to fill in dead space or to cover the prosthesis (**TECH FIG 4**).
- If the flap is too bulky, it may be thinned by carefully removing tissue from the deep fat layer and part of the superficial fat layer, except for a few centimeters of a cuff of subcutaneous tissue around the entry point of the perforator(s). The use of loupe magnification or even the microscope may be advised to avoid damaging small blood vessels traveling through the fat.
- The wound is closed with placement of closed suction drains under the flap to prevent fluid collection (**TECH FIG 5**).
- A leg splint is applied for immobilization, and an elastic bandage is loosely

applied so as to avoid compression over the vascular pedicle.

- Part of the flap is left open for postoperative monitoring of flap perfusion.

TECH FIG 4 • A. Harvested muscle chimeric perforator flap. **B.** After end-to-end microanastomoses to the corresponding vessels of the chosen free flap, exposed artificial bone and knee joint are seen in anterior knee. **C.** Muscle component of chimeric flap is arranged to cover the artificial implant. **D.** Transferred muscle chimeric TDAP flap in anterior knee after final inset, using the medial sural vessel as recipient.

TECH FIG 5 • A. Transferred muscle chimeric TDAP flap in posterior knee after final inset, using the medial sural vessel as recipient. **B.** Transferred TDAP flap in medial knee after final inset, using muscular branch of the descending genicular vessel as recipient. **C.**

Transferred DIEP flap in anterior knee after final inset, using muscular branch of the descending genicular vessel as recipient. **D.** Transferred TDAP flap in lateral knee after final inset, using the superolateral genicular vessel as recipient.

PEARLS AND PITFALLS

Planning

- Meticulous preoperative planning for recipient vessels, donor site, flap composition, and positioning of the patient is crucial for successful reconstruction.
- A multidisciplinary approach with comprehensive communication between oncologic and/or orthopedic surgeons will enable better treatment outcomes.

Selection of recipient vessel

- The recipient vessel option includes the descending genicular vessel and its branches, descending branch of lateral circumflex femoral vessel and anterior tibial vessel in the anterior knee, and superior medial and lateral genicular vessel, medial and lateral sural vessel, middle genicular vessel, and inferior genicular vessel in the popliteal area. Surgeons may choose a recipient vessel based on the proximity to the defect, concomitant injuries, vessel availability, and vessel size match.
- The deep vein system is usually considered as the first choice of recipient vein for a free flap in the lower extremity. However, in this anatomical area of the knee, a superficial vein such as the great saphenous vein is sometimes in a more convenient position and is a better size match for anastomosis than the deep vein system.

Assessment of the defects

- Free flaps in this region should provide ample skin coverage to allow unrestricted joint mobility in flexion and extension and to facilitate ambulation.
- Defect size and shape are exactly measured by making a template for subsequent flap design.

Microanastomosis and flap inset

- It is important to avoid twisting and kinking of the pedicle.
- Tension on the pedicle should be avoided and sufficient

acquisition of pedicle length is a safe strategy.

- Defatting of the perforator flap at the time of inset is an effective technique to obtain aesthetic contour but must be performed carefully to avoid compromising blood supply.

POSTOPERATIVE CARE

- Most surgeons who perform free flaps in the lower extremity rely upon clinical observations including subjective visual inspection, capillary refill, turgor, and temperature of the flap, in combination with a handheld pencil Doppler for monitoring the flap.¹⁶ The protocol varies according to surgeon, but the authors perform clinical assessment of flap status, combined with a handheld Doppler examination, every 3 hours for the first 48 hours and then every 6 hours for the next 48 hours after surgery.
- Although preferences regarding anticoagulation regimens vary widely among microvascular surgeons, medication for perioperative anticoagulation can be used to minimize the risk of postoperative thrombosis. The major classes include antiplatelet, heparin-based anticoagulant, and plasma expander drugs.
- Postoperatively, lower extremity edema and overly aggressive mobilization can compromise the free flap, especially causing venous congestion.¹⁷ Although the duration of immobilization time varies based on the orthopedic injuries, generally progressive weight bearing and ambulation are achieved when the patient is tolerating dangling at least 30 minutes, six times per day.¹⁷
- Postoperative rehabilitation to maintain knee movement is an essential part of treatment and should be commenced in the early postoperative period.¹⁵

OUTCOMES

- Published success rates for free tissue transfers to the knee vary according to the etiology of the defect, but a microvascular free flap in this region is a safe procedure, with a success rate ranging from 97% to 100%.^{1,15,18}
- A microvascular free flap is a reliable reconstructive option for defects of various sizes in various locations in the knee. The type of perforator flap, whether cutaneous or muscle chimeric (**FIG 3**), is selected according to tissue requirement.

COMPLICATIONS

- Vascular complications such as venous and arterial thrombosis
 - Prompt emergent exploration is demanded when these conditions are

suspected.

- Hematoma

- Early diagnosis of a hematoma under the flap is critical so that it can be evacuated promptly to prevent compression of the anastomotic site due to an expanding hematoma. Any time a postoperative hematoma is noted, the surgeon must suspect venous obstruction.

- Infection

- When the defect accompanies an infected prosthesis and chronic infection of the bone or joint, a late infection or recurrence of infection after free tissue transfer can develop.^{18,19} Therefore, it is critical that the wound be sufficiently debrided of necrotic, infected, or pathologic tissue before definitive flap reconstruction.

- Suboptimal knee range of motion

- Suboptimal knee range of motion may result from increased periods of restricted knee extension followed by allowance of very limited knee range of motion during free flap maturation.¹ Therefore, early range of motion is advised once flap viability is established.

FIG 3 • A,B. Satisfactory result of muscle-chimeric free flap to the posterior knee defect.

CHAPTER Repair of Patella Tendon

Patrick Horrigan, Michael Bellino, and Julius Bishop

DEFINITION

- Rupture of the patellar tendon is a disruption of the knee extensor mechanism between the patella and the tibial tubercle.
- Complete ruptures cause significant disability, pain, hemarthrosis, and an inability to extend the knee.
- Prompt treatment nearly always involves surgery and early motion during rehabilitation.
- Missed or delayed diagnosis and treatment can result in significant pain and dysfunction.¹

ANATOMY

- The patellar tendon is a continuation of the quadriceps tendon, a confluence of the vastus medialis, intermedius, and lateralis tendons and the rectus femoris tendon. It is derived primarily from extending fibers of rectus femoris traversing the anterior surface of the patella.
- The tendon itself consists of 90% type I collagen. Its fibers are arranged longitudinally relative to the axis of the lower extremity.
 - It measures approximately 32 mm in width and narrows by several millimeters near its insertion on the tibial tubercle.
 - Its thickness in normal knees is approximately 6 mm at its proximal extent and 6 mm distally.^{2,3}
- The blood supply of the patellar tendon is derived from the inferior genicular arteries proximally and from the anterior tibial recurrent artery distally. It shares a portion of its blood supply posteriorly with the infrapatellar fat pad.^{3,4}

PATHOGENESIS

- Because degenerative changes are present in most cases, tendinopathy is increasingly given the primary pathogenic role in rupture.⁵
- Rupture can also occur in the setting of direct trauma, recent corticosteroid injections for tendonitis, and systemic disease (patients with chronic acidosis or nephropathy requiring hemodialysis, systemic lupus erythematosus).⁶
- A classic described mechanism is forceful contraction of the quadriceps musculature with the knee in greater than 45 degrees of flexion.⁷

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients will typically describe an acute popping or tearing sensation during a brief period of forceful quadriceps contraction. This is often followed by acute-onset knee pain, swelling, and inability to bear weight.
- A palpable infrapatellar defect around a swollen joint can sometimes be appreciated on the symptomatic knee.

IMAGING

- Plain anteroposterior and lateral radiographs of the knee are usually sufficient for diagnosis of patella tendon rupture (**FIG 1**).⁷
- In cases of uncertain physical examination, MRI or ultrasonography may be useful for confirmation of diagnosis.

DIFFERENTIAL DIAGNOSIS

- Quadriceps tendon rupture
- Patella fracture
- Medial/lateral collateral ligament rupture
- Anterior cruciate ligament rupture
- Meniscus tear
- Patellar dislocation/subluxation event

NONOPERATIVE MANAGEMENT

- Management of patellar tendon ruptures in medically stable adults is surgical. Nonoperative treatment predictably results in tendon retraction and loss of active knee extension strength and extensor lag.⁷

FIG 1 • A,B. Anteroposterior and lateral radiographs of a 32-year-old man with a sudden popping sensation and left knee pain after landing from a jump while playing basketball. Radiographs show a knee effusion, absence of fracture and patella alta best seen on the lateral projection.

SURGICAL MANAGEMENT

- Surgical goals include restoration of the knee extensor mechanism with strength to allow for early postoperative rehabilitation.
- Secondary goals include avoidance of overcorrection resulting in patella baja and altered knee kinematics.
- The most commonly described technique to date consists of an augmented primary repair using transosseous patellar tunnels and nonabsorbable suture fixation.⁸

Preoperative Planning

- AP and lateral radiographs of the affected and contralateral knee can be reviewed for comparison and to look for other concurrent abnormalities such as calcific tendonitis, abnormal patellar morphologies, or previous surgeries.

Positioning

- The patient is positioned supine on a radiolucent table with arms abducted. A bump is placed under the ipsilateral buttock and low back to facilitate internal rotation of the operative knee to neutral.
- A nonsterile tourniquet is applied.

- Hair over the operative site and anticipated dressing placement is trimmed with clippers.
- C-arm fluoroscopy may be available for confirmation of tunnel placement or for delineation of any occult fracture fragments not noted on initial radiography.

Approach

- An anterior approach to the patellar tendon provides the most direct and extensile access to the site of injury and planned repair.

TECHNIQUES

■ Transosseous Suture Technique

Anterior Approach to the Patellar Tendon and Extensor Retinaculum

- Landmarks: patella, tibial tubercle, and patellofemoral joint line.
- Exsanguinate the leg and inflate a tourniquet as needed for hemostasis
- Make a midline incision longitudinally from the superior pole of the patella to the proximal aspect of the tibial tubercle.
- Elevate thick skin flaps to the prepatellar bursa. Hematoma is often encountered at this point.
- Identify patellar paratenon for later repair if not traumatically disrupted.
- Identify the area of patellar tendon rupture and the extent of retinacular involvement.
- Evacuate intra-articular hematoma.

Preparation of Tendon

- Identify the area of the tear; most patellar tendon ruptures are from the distal patellar pole, leaving a long distal limb for suture anchoring.
- Debride the tendon and infrapatellar pole of any nonviable strands or areas of degeneration and thickening. Excise any free bony fragments that originated from the inferior patellar pole that cannot be incorporated into the repair construct.
- Using two separate thick nonabsorbable braided suture (no. 5 FiberWire) and

starting at the most proximal aspect of the distal segment, pass the Krackow sutures on either side of the tendon, traversing for approximately four or five passes before creating a second row per suture and ultimately creating four total suture strands exiting near the suture's entry point (**TECH FIG 1**).

- Separate the four strands into three groups: one medial, two central, and one lateral. Cut the central strands to two different lengths that can still pass through the length of the patella and be tied down. This will differentiate them during suture fixation.

TECH FIG 1 • A. Diagram of Krackow suture repair of torn patellar tendon. **B.** Left knee patellar tendon repair with four-strand Krackow sutures placed.

Creation of Bone Tunnels

- Identify the medial and lateral borders of the patella. Divide this total width into fourths, taking into account areas of thin cortical bone, particularly at the lateral facet.
- Using a long 2.5-mm drill, create three retrograde drill holes at the central divisions of each of the zones described in step one (**TECH FIG 2**). Mark the entry point of each drill pass with electrocautery. Consider using multiple drill bits or saved fluoroscopic views to ensure the drill paths do not cross.

Suture Passage and Knot Tying

- Flex the knee to approximately 20 degrees with a small bump behind the knee. This is to ensure suture passage anterior to the quadriceps tendon to permit knot tying as close to the patella as possible.
- Use a 2.4-mm Beath pin with eyelet to pass each of the four suture strands through the three drill holes using the designation created earlier. All strands will then be superior to the patella (**TECH FIG 3A–C**).
- Pass the central limbs through the quadriceps tendon to their corresponding medial and lateral limbs using a free needle. This avoids soft tissue bridging and possible loosening (**TECH FIG 3D,E**).
- Hand tie at least five surgical knots, using a slip knot or needle driver to hold the initial knot tight. Leave 4-mm tails of suture.

TECH FIG 2 • Drill holes placed retrograde with long 2.5-mm drill.

Completion and Assessment of Repair

- Repair any ruptured retinaculum with large absorbable braided suture.
- Move the knee through passive motion under direct visualization of repair.
 - Note any gapping or opening of the repair. This will be the limit of range of motion in the early postoperative period.
- Deflate tourniquet, irrigate, obtain hemostasis, and close in layers with paratenon closure if possible.
- Apply a soft dressing and a hinged knee brace locked in extension.

TECH FIG 3 • **A.** Beath pin passed retrograde through each of three marked drill holes. **B.** Threaded Beath pin passing through central drill hole with two suture strands. **C.** Central thread strands now passed through drill hole and quadriceps tendon with knee slightly flexed. **D.** Free needle used to pass central suture strands closer to their respective medial and lateral strands so as to avoid soft tissue bridging. **E.**

All four suture strands ready for creation of two hand-tied knots.

PEARLS AND PITFALLS

Indications	■ Confirm diagnosis with examination under anesthesia to rule out the more proximally oriented quadriceps tendon rupture.
Tendon preparation	■ Ensure at least three passes of each row of Krackow suture to limit the possibility of suture pullout and subsidence of fixation.
Creation of bone tunnels	■ Avoid intra-articular penetration of drill, using fluoroscopic guidance or via proprioceptive feedback with the patella held between the thumb and index finger. ■ Oscillate when drilling tunnels so as not to bind suture in drill bit. ■ Mark bone tunnel placement in surrounding soft tissues with electrocautery for accuracy of Beath pin passage. ■ Avoid crossing of bone tunnels, which can create suture entanglement and prevent secure tightening of repair knots.
Suture passage and knot tying	■ Use a free needle to pass suture close to its accompanying strand and avoid soft tissue bridging. ■ Avoid over- or undertensioning of suture and subsequent alteration of patellofemoral mechanics.

POSTOPERATIVE CARE

- In isolated tendon injuries, the patient may be discharged to home with hinged knee brace locked in extension for 2 weeks. No active knee extension is permitted for 6 to 8 weeks.
- At the initial 2-week postoperative follow-up visit, the brace is unlocked for range of motion exercises up to the limit noted at the time of operation.
- Thirty-degree increases may be made every 2 weeks, and then knee brace is unlocked and weaned entirely for the remainder of rehabilitative therapy.
- Stretching and strengthening are permitted at 8 weeks, with return to full activity as tolerated at 12 to 16 weeks.

OUTCOMES

- Gilmore et al. analyzed the different techniques of acute and chronic patellar tendon repair in a recent review.⁹
- In searching techniques of primary repair, they noted 383 patellar tendon ruptures repaired primarily.
 - Seventy-seven percent of the primary repairs were with nonabsorbable suture.
 - Sixty-six percent of primary repairs underwent some form of augmentation.
 - The most common suture method was the Krackow technique.
- Five different outcome scoring systems were used to grade the success of repair.
 - While no comparisons in functional outcome could be made between specific techniques, primary repairs with augmentation demonstrated the best mean knee range of motion of 0 to 129 degrees.
- Augmented primary repair also demonstrated the lowest failure rate at 2%.

COMPLICATIONS

- In Gilmore et al.'s review,⁹ augmented primary repair demonstrated the lowest failure rate at 2%.
- Described complications of patellar tendon repair include¹:
 - Improper tendon tensioning leading to patella alta or baja
 - Failure of repair/ rerupture
 - Infection
 - Knee stiffness
 - Prominent suture knots requiring removal
 - Deep vein thrombosis

Section IV: Thigh

35 Excision of Soft Tissue Tumors of the Thigh

CHAPTER

Raffi S. Avedian

DEFINITION

- Soft tissue sarcomas are malignant tumors that arise from mesenchymal cells and are classified according to their cell of origin such as the muscle, tendon, or fat.
- Peripheral nerve sheath tumors arise from neural crest cells but are typically grouped with sarcomas because of similarities in location, natural history, and treatment.
- The World Health Organization groups soft tissue sarcomas into ten categories based on the tissue of origin.
- Most sarcomas occur in a deep location meaning below the muscle fascia, whereas one-third of sarcomas occur in a subcutaneous location.
- Patients with soft tissue sarcomas and patients with benign tumors often present with the same chief complaint of having a soft tissue mass.
- Rendering an accurate diagnosis prior to surgery is important because the treatment plan may vary based on the nature of the diagnosis. For example, a benign tumor may be monitored or removed with a simple excision, whereas in the case of a sarcoma, the goal of surgery is to remove the tumor with a wide margin.
- With appropriate planning, radiotherapy and/or chemotherapy is often incorporated into the treatment plan either before or after definitive surgery.¹

ANATOMY

- The critical anatomic structures that should be preserved when performing an excision of tumor in the thigh are the femoral artery, sciatic nerve, and femoral nerve.
- The common femoral artery enters the thigh under the inguinal ligament. As it travels distally, it gives several branches, the largest of which is the profunda femoral artery (PFA). This branch travels on top of the adductor brevis until the muscle inserts onto the linea aspera at which point the distal half of the PFA continues just posterior to the femur.
- Several perforator branches from the PFA pierce the lateral intermuscular septum and go into the anterior compartment. In most patients, limb salvage can be performed even if the PFA is ligated near its takeoff from the common femoral artery.
- The superficial femoral artery (SFA) is the most important blood vessel when considering tumor excision. It must be preserved or reconstructed if excised to maintain viable limb perfusion. As the SFA travels distally, it is located on the anterior surface of the psoas, adductor longus, and then adductor magnus until it courses through the adductor canal into the popliteal fossa. The sartorius muscle acts as a cover to the superficial femoral vessels throughout the middle of the thigh.
- There are three muscle compartments of the thigh: anterior, medial, and posterior.
- The sciatic nerve travels in the posterior compartment. It branches into the common peroneal nerve, which can reliably be dissected and found just medial and anterior to the biceps femoris in the popliteal fossa. The tibial nerve portion of the sciatic nerve stays midline with the popliteal vessels.
- The femoral nerve divides into several branches that spread out and innervate the anterior compartment muscles soon after passing under the inguinal ligament. Unlike the sciatic nerve, which can be isolated throughout the thigh, the femoral nerve is rarely identified during tumor removal because it branches so proximally.

PATHOGENESIS

- The mechanism for sarcoma formation is not known.
- Risk factors for sarcoma development include radiation exposure, radiotherapy, pesticide exposure, and hereditary conditions including Li-Fraumeni syndrome and neurofibromatosis.

NATURAL HISTORY

- All sarcomas have the potential for local recurrence and metastasis.
- Tumor variables that are associated with increased risk of metastasis include high grade and large size (greater than 5 cm).²
- Lungs are the most common location of metastasis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Determining when the mass was first noticed and how rapidly it is growing can help the clinician differentiate between benign and malignant tumors.
- The presence of pain is often associated with a benign tumor such as a schwannoma or vascular malformation and may not be present with sarcomas until late in the disease course.
- Determining the size of the tumor, manual muscle strength testing, and sensory examination are useful to determine if there is neurological compromise. Limb edema assessment and pulse examination can help determine if the tumor is causing vascular or lymphatic compromise.
- Range of motion testing and gait assessment are helpful in assessing a patient's mobility and functional status to guide a perioperative and postoperative counseling.

IMAGING

- Magnetic resonance imaging is the modality of choice for soft tissue tumor evaluation.³
- Fat-sensitive images such as T1-weighted sequences are best for identifying critical anatomic structures such as nerves and vessels (**FIG 1**).
- Fluid-sensitive images including T2-weighted and STIR sequences highlight pathology very well.
- Contrast-enhanced sequences are used to differentiate cystic from solid areas in tumors and identify reactive peritumoral edema, which will be high signal on fluid sequences but not enhance with contrast.
- Some benign tumors such as lipoma and schwannoma may be diagnosed on MRI; however, most soft tissue tumors require a biopsy for diagnosis.

DIFFERENTIAL DIAGNOSIS

- Benign tumors
- Sarcoma
- Lymphoma of soft tissue

■ Infection/abscess

FIG 1 • Axial T1-weighted image demonstrating compartments of the thigh and relevant anatomy of the thigh. The *arrow* points at the sciatic nerve and the *arrowhead* at the femoral vessels, and there is a sarcoma in the vastus medialis.

SURGICAL MANAGEMENT

- The appropriate treatment for any musculoskeletal tumor is based on its diagnosis and natural history.
- Performing a surgery without consideration of the diagnosis and the appropriate margin may cause harm to patients.⁴
- In cases where MR imaging is not diagnostic, a biopsy should be performed.
- Treatment strategy including the use of preoperative radiation and specific surgical plan should be formulated by a multidisciplinary team specializing in sarcoma care.

FIG 2 • A. Axial MRI of the thigh demonstrating a subcutaneous sarcoma. **B.** Coronal MRI of the thigh showing a subcutaneous sarcoma.

Preoperative Planning

- A patient is considered ready for surgery after completion of staging and multidisciplinary review of pertinent imaging, pathology, and treatment strategy.
- The surgical plan is created by thorough study of the preoperative MR scan. A plane of surgical dissection is planned to remove the tumor in its entirety while maintaining a clean margin around it (**FIG 2**).
- If the tumor encases important vascular structures, a plan for vascular reconstruction is made with a vascular surgeon.
- Anticipated soft tissue coverage needs are assessed such as skin graft, local rotation flap, or free tissue transfer.

Positioning

- The patient is placed in the supine position when the tumor is in the anterior or medial compartment (**FIG 3**).
- The patient is placed in the prone position when the tumor is in the posterior compartment.
- The site of a flap harvest must be completely isolated from the tumor site to avoid contamination and tumor spread. A separate back table and clean instruments should be used.

FIG 3 • Intraoperative photograph demonstrating patient positioning.

Approach

- The surgical approach varies based on the location of the tumor.
- Previous biopsy and surgical scars are considered contaminated and must be excised en bloc with the tumor.

TECHNIQUES

■ Wide Resection of Subcutaneous Sarcoma

- Subcutaneous sarcomas are located in the adipose tissue above the muscle fascia. There is no anatomic barrier to longitudinal tumor spread in this location; however, the deep fascia can act as a natural barrier to deep penetration of the tumor. Careful review of preoperative MR imaging and physical palpation are important when determining tumor extent and the location of the surgical incision.
- A surgical incision is planned 2 cm to 3 cm peripheral to the edge of the tumor as determined by palpation and MRI. Typically, a large paddle of the skin is removed along with the tumor (**TECH FIG 1**).
- The dissection is carried through the subcutaneous fat angling away from the tumor.
- The deep fascia is identified and cut circumferentially around the tumor.
- The fascia and subcutaneous tissue containing the tumor are kept in

continuity, and a small cuff of muscle is removed with the fascia to ensure a clean deep margin.

- The tumor and surrounding fat, fascia, and muscle are removed in their entirety.
- Take care not to shear off the fat from the fascia during dissection.
- Avoid retractors on the tumor side of the dissection.
- Most surgeries require a skin graft or muscle flap for closure. Do not sacrifice margin to save tissue for a primary closure.

TECH FIG 1 • Operative technique for resecting a subcutaneous sarcoma. **A.** Dissection of the skin and subcutaneous tissue around the tumor, notice the large paddle of skin that extends approximately 2 cm beyond the palpable tumor to ensure adequate resection margin. **B.** Dissection through the deep plane leaving the fascia and small, approximately 1-cm, cuff of underlying muscle on the tumor that serves as the deep margin. **C,D.** The skin was then reapproximated, and preparation for skin grafting was completed. **E.** A split-thickness skin graft was obtained from the contralateral thigh using completely separate instruments, back table, and clean gowns and gloves

to avoid seeding the harvest site with tumor.

■ Wide Resection of a Deep Sarcoma

- Because fascia acts as a natural anatomic barrier, tumors tend to grow longest in a longitudinal dimension; as a result, larger margins in the longitudinal plane compared to the mediolateral/anteroposterior planes are recommended.
- Tumors often abut major nerves and blood vessels in which case the epineurium around the nerve and adventitia surrounding the vessel can be used as margins⁵ (**TECH FIG 2**).

TECH FIG 2 • **A.** Axial T1 fat-suppressed contrast MRI showing a high-grade sarcoma within the vastus medialis and abutting the femoral artery and vein. **B.** Coronal T1 fat-suppressed contrast MRI. **C.** Axial T1 fat-suppressed contrast MRI after completion of preoperative radiation showing decreased enhancement suggesting tumor necrosis.

■ Incision and Dissection

- A longitudinal incision is made over the tumor by incorporating the previous biopsy site.
- Subcutaneous skin flaps are raised circumferentially around the tumor making sure to keep the deep fascia intact as a margin around the tumor.

- Begin the deep dissection by palpating the tumor and incising the deep fascia several centimeters further out from the tumor. If the tumor abuts the fascia, then leave the fascia intact, trace it back to its insertion on the bone, and remove it in its entirety as a margin around the tumor thus avoiding inadvertent tumor penetration or exposure (**TECH FIG 3**).
- It is recommended that several centimeters of muscle be removed from cranial and caudal to the tumor. The decision on how much muscle to remove is based on preoperative evaluation of the MRI, palpation of the tumor, and visual inspection of the muscle to ensure the plane of dissection is outside of the tumor and any associated abnormal tissue such as a pseudocapsule.
- If the tumor abuts the bone but there is no evidence of bone penetration, use a periosteal elevator to lift the periosteum off the bone with the tumor on top. The periosteum acts as the deep margin.
- If there is bone penetration, then depending on the extent of bone involvement, either a hemicortical or complete resection should be performed and reconstructed with either allograft, vascularized fibula, or endoprosthesis.
- If the tumor encases the major blood vessels of the limb, they should be removed en bloc with the tumor followed by vascular reconstruction.

TECH FIG 3 • Operative technique for resection of a deep sarcoma of the thigh. **A.** Photograph showing deep dissection of tumor, * indicates proximal end of sartorius, X indicates cut distal end of adductor magnus. The adventitia of the vessels are dissected and left with the tumor. **B.** Photograph showing complete mobilization of the vessels, the medial intermuscular septum and vessel adventitia “*” serve as the deep margin. **C.** Photograph after the remaining muscles around the tumor are cut and the

tumor is removed with a clean margin. The wound is closed in layers with multiple suction drains.

■ Completion

- After tumor removal, irrigate the wound thoroughly and assess the dead space. An attempt to myodese (muscle-to-muscle approximation with sutures) surrounding muscles to eliminate as much dead space as possible is recommended.
- Other strategies to manage dead space are local or free muscle transfer, closing over multiple drains, and rarely delayed closure using a negative pressure dressing.

PEARLS AND PITFALLS

Hematoma	■ Dead space after tumor removal should be managed with drains, muscle flap, free tissue transfer, or a combination of these techniques. ■ Seroma drainage in the clinic may be necessary.
Wound breakdown	■ Incisional negative pressure dressings, aggressive dead space management, and maximizing patients' nutrition may reduce wound problems. ■ Patients should be counseled about potential need for reoperation for wound management.
Positive margins	■ Appropriate preoperative planning is important to minimize risk of unplanned positive margins. ■ Planned positive margins around critical structures such as nerves and vessels may be appropriate in certain settings.

POSTOPERATIVE CARE

- Mobilization and weight bearing depend on the extent of surgery.
- Extremity elevation is recommended while patient is in bed.
- Range of motion and therapy may begin after wound healing is sufficient.
- Postoperative radiotherapy may take place 4 to 6 weeks after surgery.

OUTCOMES

- Oncological outcomes include local recurrence and metastasis. Surveillance for recurrence should be managed by a multidisciplinary sarcoma team.
- Functional outcomes depend on the extent of tissue resection, patient overall health status, and late effects of radiation. Aggressive wound care and physical therapy may help maximize patient function.^{6,7}

COMPLICATIONS

- Wound healing problems that require operative intervention can occur in up to 33% of patients who undergo preoperative radiotherapy and 17% of patients who undergo postoperative radiotherapy.¹
- Local recurrence occurs in a minority of patients and is more common in patients with positive margins. Radiotherapy decreases the risk of local recurrence.

36 Excision of Bone Tumors of the Femur

CHAPTER

Raffi S. Avedian

DEFINITION

- Bone tumors of the femur may be benign or malignant (bone sarcoma) and exhibit a variable natural history ranging from latent to rapid growth. Aggressive benign tumors and malignant tumors typically cause pain, dysfunction, and fracture.

ANATOMY

- The femoral artery, sciatic nerve, and femoral nerve are important structures that need to be accounted for during surgery of the femur.
- The common femoral artery enters the thigh under the inguinal ligament. As it travels distally, it gives several branches, the largest of which is the profunda femoral artery (PFA), which travels on top of the adductor brevis until the muscle inserts onto the linea aspera at which point the distal half of the PFA continues just posterior to the femur.
- Several perforator branches from the PFA pierce the lateral intermuscular septum and go into the anterior compartment. The PFA is located near the linea aspera and is often ligated when resecting segments of the femur.
- The superficial femoral artery (SFA) is the most important blood vessel when considering tumor excision. It must be preserved or reconstructed if excised, to maintain viable limb perfusion. As the SFA travels distally, it is located on the anterior surface of the psoas, adductor longus, and then adductor magnus until it courses through the adductor canal into the popliteal fossa. The sartorius muscle acts as a cover to the superficial femoral vessels throughout the middle of the thigh.
- The sciatic nerve travels in the posterior compartment. It branches into the

common peroneal nerve, which can reliably be dissected and found just medial and anterior to the biceps femoris in the popliteal fossa. The tibial nerve portion of the sciatic nerve stays midline with the popliteal vessels.

PATHOGENESIS

- The mechanism for bone tumor formation is not known.
- Risk factors for sarcoma development include radiation exposure, radiotherapy, pesticide exposure, and hereditary conditions including Li-Fraumeni syndrome and retinoblastoma gene mutation.

NATURAL HISTORY

- Active benign tumors, such as giant cell tumor of the bone, chondroblastoma, and aneurysmal bone cyst, will progress over time and may recur after excision but are not lethal.
- All bone sarcomas have the potential for local recurrence and metastasis.
- Some bone sarcomas such as low-grade chondrosarcoma exhibit a slow rate of growth and low risk of metastasis, whereas aggressive tumors like high-grade osteosarcoma and dedifferentiated chondrosarcoma grow rapidly and have a relatively high risk of metastasis.
- Tumor variables that are associated with increased risk of metastasis include high grade and large size (greater than 8 cm).
- Lungs and other osseous sites are the most and second most common location of metastasis, respectively.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pain is a common presenting symptom for aggressive bone tumors.
- A thorough history and examination are important to assess duration of symptoms, comorbidities, physical dysfunction, organ involvement, overall health, and patient expectations to best tailor treatment strategy for the individual patient.
- Neurovascular examination is mandatory for any extremity tumor.

IMAGING

- Plain radiographs are used to formulate a differential diagnosis and a preoperative plan (**FIG 1A**).
- Magnetic resonance imaging is routinely used to determine the extent of intramedullary tumor involvement, presence of soft tissue extension, status of the neurovascular structures, and preoperative planning (**FIG 1B**).

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for a bone tumor includes benign tumors, sarcomas, lymphoma of the bone, infection, and metabolic lesions (eg, hyperparathyroidism).
- The most common bone sarcomas are osteosarcoma, chondrosarcoma, and Ewing sarcoma.

SURGICAL MANAGEMENT

- The appropriate treatment for any musculoskeletal tumor is based on its diagnosis and natural history.
- Biopsy incisions are considered contaminated and must be resected at the time of definitive surgery. Care should be taken to place the biopsy in a location that does not interfere with the final surgical plan.

FIG 1 • A. Anteroposterior radiograph of a 67-year-old man with high-grade chondrosarcoma of the proximal femur seen as a large lucent lesion. **B.** Coronal T2-weighted MRI of the same patient demonstrating extensive soft tissue component and intramedullary involvement by chondrosarcoma.

- Intralesional curettage is the preferred treatment for benign tumors. Radical resection with a clean margin is required for bone sarcomas.
- Reconstruction depends on the extent of bone excision and may include simple bone grafting, endoprosthetic implants, bulk allografts, osteoarticular implants,

or vascularized fibula.

- The goal of surgery is to remove the tumor adequately to minimize recurrence and restore the mechanical integrity of the bone and joints so that the patient may have sufficient function to perform activities of daily living with minimal pain.^{1,2}

Preoperative Planning

- A patient is considered ready for surgery after completion of staging and multidisciplinary review of pertinent imaging, pathology, and treatment strategy.
- The surgical plan is created by a thorough study of the preoperative radiographs and MR scan.
- Bone cuts are planned by examining preoperative imaging and measuring the distance from an intraoperatively identifiable landmark (eg, femoral condyle, greater trochanter) to the desired osteotomy site.
- The soft tissue margin depends on the size and location of a soft tissue component to the tumor. For example, an anterior soft tissue mass along the distal femur can be safely resected by incorporating a portion of the vastus intermedius as the margin.
- When tumor abuts but does not encase blood vessels or nerves, they can be dissected free by leaving adventitia and epineurium on the tumor as the margin.

Positioning

- Patient positioning is based on the surgeon's assessment of the critical anatomy of the surgery and how best to visualize it during surgery.
- Distal femur resections are typically performed in the supine position. Proximal femur tumors are often performed in the lateral position.
- If a flap is to be used, the harvest must be performed using a separate back table and instruments and the surgical sites completely isolated to avoid contamination.

Approach

- The surgical approach varies based on the location of the tumor.
- Previous biopsy and surgical scars are considered contaminated and must be excised en bloc with the tumor.

TECHNIQUES

■ Femur Resection and Allograft Reconstruction

- Tourniquet is used at discretion of the surgeon using gravity exsanguination rather than Esmarch to avoid tumor dissemination.
- A longitudinally oriented incision is created that includes a fusiform skin excision of the biopsy site. Skin flaps are created as needed to ensure adequate visualization of the tumor and critical anatomy.
- Dual incisions may be useful for hemicortical resection, but otherwise are rarely used.
- Soft tissue dissection around the tumor is performed with the following principles:
 - Adequate visualization must be achieved.
 - Margin of healthy tissue is kept on the tumor.
 - Nerves are dissected free. The epineurium may be used as margin if tumor abuts the nerve. Sciatic nerve branches to hamstring muscles may be cut as needed to adequately mobilize nerve away from tumor.
 - Vessels are mobilized and the adventitia may be used as margin if tumor abuts the vessels.
- Bone cuts are performed based on preoperative planning and measurements to ensure complete tumor removal. Easily identifiable anatomic landmarks such as the femoral condyles, epicondyles, greater trochanter, and vastus ridge serve as reference points for measurements that can be transferred from preoperative plans to intraoperative execution.
- Fluoroscopy may be used at the discretion of the surgeon.
- Hemicortical resection is an option if the tumor does not involve the entire diameter of the bone.
- Reconstruction is performed to restore mechanical stability of the extremity.
 - Endoprosthetic implants, if used, may be cemented or press fit into the native bone.
 - Allografts are fashioned to fit the defect and secured in place with internal fixation (**TECH FIG 1**).
- The deep fascia, if available, is closed over drains, followed by a subcutaneous fascia and dermal layer. Deep drains are used to avoid

hematoma and minimize pressure on the skin repair.

TECH FIG 1 • **A.** Anteroposterior radiograph of a 74-year-old man demonstrating bone sarcoma with soft tissue mass. **B.** Axial T1-weighted MRI showing tumor eroding into femur and abutting sciatic nerve and popliteal vessels. **C.** Sagittal MRI showing craniocaudal extent of tumor. **D.** Intraoperative photograph demonstrating soft tissue dissection to expose tumor, mobilize popliteal vessels and sciatic nerve, and expose femur in preparation of osteotomy. **E.** Intraoperative photograph showing the femur after tumor resection. **F.** Allograft femur with ink lines outlining how the graft will be fashioned to fit the defect. **G.** Intraoperative photograph after allograft has been secured into the native femur. **H.** Lateral

radiograph of the distal femur 3 weeks after surgery. **I.** Lateral radiograph of the distal femur 36 months after surgery. The allograft has incorporated into the patient's femur.

PEARLS AND PITFALLS

Hematoma

- Dead space after tumor removal should be managed with drains, muscle flap, free tissue transfer, or a combination of these techniques.
- Seroma drainage in the clinic may be necessary.

Wound breakdown

- Incisional negative pressure dressings, aggressive dead space management, and maximizing patients' nutrition may reduce wound problems.
- Patients should be counseled about potential need for reoperation for wound management.

Positive margins

- Appropriate preoperative planning is important to minimize risk of unplanned positive margins.
- Planned positive margins around critical structures such as nerves and vessels may be appropriate in certain settings.

Allograft nonunion/fracture

- Common complications may be minimized by good cortical apposition of graft to the native bone.
- Restrict weight bearing until evidence of bone healing is observed.
- Counsel patients that reoperation for nonunion is possible.

POSTOPERATIVE CARE

- Mobilization and weight bearing depend on the extent of surgery.
- Extremity elevation is recommended while patient is in bed.
- Range of motion and therapy may begin after wound healing is sufficient.
- May administer antibiotics in the perioperative period.

OUTCOMES

- Oncological outcomes include local recurrence and metastasis. Surveillance

for recurrence should be managed by a multidisciplinary sarcoma team. Local recurrence is greater when margins are positive.

- Functional outcomes depend on the extent of tissue resection and patient overall health status. Most patients will experience some form of disability that is proportional to the volume of muscle and bone resected.^{3,4}

COMPLICATIONS

- Allograft nonunion and fracture are relatively common and require additional surgery to achieve a limb salvage.⁵
- Local recurrence occurs in a minority of patients and is more common in patients with positive margins.
- Deep infection can occur at any time after surgery and requires aggressive therapy including surgical debridement and antibiotic therapy to achieve limb salvage. Removal of implants may be necessary to eradicate infection.

Femoral Bone Debridement

CHAPTER

Robert J. Steffner, David W. Lowenberg, and Sahitya K. Denduluri

DEFINITION

- Femoral bone debridement is generally needed for osteomyelitis (acute or chronic), symptomatic nonunion, and open fracture.

ANATOMY

- The femur contributes to the hip and knee joints and withstands significant stress in motion.
- Vital structures around the femur include the sciatic and femoral nerves, the superficial and deep femoral artery and vein, and the extensor mechanism for knee extension.

PATHOGENESIS

- Open fracture leads to gross contamination, soft tissue stripping, and avascular bone. Direct inoculation occurs, which will lead to infection in the absence of prompt surgical care.
- Hematogenous spread of bacteria to the bone can create osteomyelitis. Acute infection tends to produce rapid symptoms and the accumulation of purulent fluid. Chronic infection is more indolent and produces waxing and waning symptoms. After a week or two of infection, bacteria form a protective avascular matrix called biofilm. Antibiotics cannot penetrate this layer.
- Nonunion is a fractured bone that will not heal. Hypertrophic nonunion comes from too much fracture site motion. Atrophic nonunion is from poor blood supply and inadequate substrate for bone healing. Infection can also lead to nonhealing bone and sometimes creates a false joint known as a pseudarthrosis.
- In all of these instances, surgical debridement is required to promote bone

recovery and healing.

NATURAL HISTORY

- Neglected open fractures and osteomyelitis can lead to systemic infection and sepsis, which is life threatening.
- Chronic infection can produce a nonhealing wound with drainage. This limits quality of life and can also lead to squamous cell carcinoma at areas of long-standing skin ulceration.¹
- Nonunion in the femur limits weight bearing and mobilization. Pain is often present with activity. Quality of life is significantly diminished.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Ask about prior trauma, surgical procedures, and any complications or wound healing problems.
- Specifically ask about cellulitis and draining sinus tracts.
- Assume infection until proven otherwise.
- Assess impact on the patient's quality of life.
- Inquire about recent antibiotic use.
- Determine host factors such as nutrition, nicotine use, medical comorbidities, use of immunosuppressive and anti-inflammatory medications, and any prior radiation exposure to the area of interest.
- Visually inspect the patient's thigh. Look for deformity, leg length discrepancy, and rotational change from the contralateral side.
- Lab work including WBC, ESR, and CRP can help determine the presence of infection.

IMAGING

- Plain radiographs can demonstrate nonhealing bone, erosive cortical changes seen in acute infection, and sclerotic thickening seen in chronic infection (**FIG 1**).

FIG 1 • **A.** AP and lateral **(B)** radiographs of a distal femur chronic osteomyelitis in the setting of prior internal fixation for an open distal femur fracture. Original hardware removed with exception of a broken screw. Radiolucent changes (*arrows*) seen in the metaphysis of a patient with clinical evidence of a draining sinus tract.

FIG 2 • **A.** Coronal and sagittal **(B)** CT scan of the distal femur with chronic osteomyelitis demonstrating sclerotic rim of the bone (involucrum) surrounding a spicule of the bone (sequestrum, *arrow*).

- Full-length, weight-bearing radiographs of the lower extremities show deformity and leg length discrepancy.

- CT scan is best for bony detail. It is the modality of choice to identify a nidus of dead bone (sequestrum) and surrounding sclerotic bone (involucrum) seen in chronic osteomyelitis (**FIG 2**).
- MRI imaging assesses the level of intramedullary bone and soft tissue involvement with bone infections. This is crucial in determining the extent of surgical debridement.

NONOPERATIVE MANAGEMENT

- Nonhealing bone and bone infection in the femur are almost always operative given the structural importance for weight bearing and ambulation.
- Exceptions include low-demand patients with minimal symptoms, patients who adapt well with assist devices, and patients at high surgical risk due to medical comorbidities.
- Nonunion patients without infection can try bracing and bone stimulation devices before surgery.

SURGICAL MANAGEMENT

- It is important to set patient expectations. Several debridement procedures may be needed to create a favorable bone and soft tissue bed for reconstructing and healing. Persistent or recurrent nonunion or infection may happen despite aggressive surgical management.

Preoperative Planning

- Address modifiable host factors including smoking cessation, nutrition, glycemic control, and medication use (anti-inflammatories, corticosteroids, etc.).
- In the lower extremity, quantify the degree of limb shortening, malalignment, and malrotation. Shortening greater than 2 cm and deformity greater than 10 degrees tend to limit a patient's quality of life.
- Anticipate the extent of debridement and appropriately plan for bony stabilization, dead space management, and soft tissue coverage.
- A reamer-irrigator-aspirator device can assist with intramedullary debridement in long bone osteomyelitis.²
- Hold antibiotics for culture. Multiple cultures should be obtained and sent for aerobic, anaerobic, fungal, and yeast assessment. Cultures will guide postoperative medical therapy.
- Send soft tissue and bone for surgical pathology. This will help determine the

presence and chronicity of infection, especially if cultures are negative.

FIG 3 • Illustration of the lateral approach to the femur.

A. The iliotibial band is divided in-line with the skin incision, and the vastus lateralis is raised off the intermuscular septum with clips placed on perforating branches of the profunda femoris artery and vein **(B)**.

Positioning

- Both lateral decubitus with an axillary roll and supine position with hip bumps and a leg ramp are acceptable for a lateral approach to the femur.
- Lateral position is best for the upper half of the femur, and supine position with leg ramp is best for the distal half of the femur.

- Use a radiolucent table to allow intraoperative fluoroscopy.

Approach

- Planned access to the femur is generally through a lateral approach (**FIG 3**). Traumatic wounds and prior incisions can sometimes lead to alternative approaches.

TECHNIQUES

■ Debridement of Chronic Osteomyelitis of the Distal Femur

- Patient is positioned supine with an ipsilateral hip bump on a radiolucent table. A small leg ramp can be added to facilitate intraoperative imaging.
- Antibiotics are held for culture and then given.
- Open wounds are prepped with Betadine scrub and paint.
- Before incision, the involved anatomic location is identified with intraoperative fluoroscopy.
- A straight lateral incision is made.
- Compromised skin is generally characterized as multiply operated, puckered, and adherent. This skin, in addition to any sinus tracts, should be sharply excised. Remaining skin should have bleeding edges.
- The iliotibial band is split in-line with the skin incision, and the vastus lateralis muscle is raised off the lateral intermuscular septum. The muscle is retracted upward to identify perforating vascular branches from the deep profunda artery and vein.
- Ligating branches with surgical clips preserves branches for possible microsurgical anastomosis.
- Using a combination of a microsaw, osteotomes, and high-speed bur, a long cortical window is created in the lateral femoral cortex. The high-speed bur is then used from inside-out to widen the elongated ellipse to improve access to the intramedullary canal (**TECH FIG 1A**). Irrigating during use of the bur can limit heat necrosis of the bone.
- Multiple cultures are obtained from the soft tissue and bone. The bone is sent for surgical pathology.

- Aggressive debridement involves excision of all nonviable soft tissue and bone (**TECH FIG 1B**), including sequestra (**TECH FIG 1C**). Surgical tools for debridement include curettes, rongeurs, osteotomes, high-speed bur, and fresh surgical blades.
- Wound irrigation is performed with low-flow cystoscopic tubing. Many liters of normal saline with antibiotics are advised.
- An adequately debrided field demonstrates bleeding tissues with normal color and properties such as contractility.
- Polymethyl methacrylate (PMMA) is mixed with medications to create filler for the defect created from the debridement. The medications used, which may include antibiotics, antifungals, and antiparasitics, should be discussed before surgery with infectious disease and pharmacy colleagues.
- Appropriate drug concentrations with PMMA should also be discussed with a pharmacist.
- PMMA beads can be made either by hand or with a mold. A line of beads is placed along a thick monofilament suture. It is important to document the number of beads being implanted.
- Pack the dead space with antibiotic beads (**TECH FIG 1D**).
- Surgical stabilization should bridge the defect. Options include external fixation, an antibiotic-impregnated cement intramedullary nail, or a locking plate coated in antibiotic cement (**TECH FIG 1E,F**).
- Final fluoroscopic or radiographic images should be taken to document implants.
- Deep drains are utilized to help with dead space management.
- Remaining soft tissues should be healthy and bleeding. Attempt to isolate deep fascial layers for a tiered closure. Primary closure should not have a lot of tension. The surgeon should maintain a low threshold for rotational or free tissue coverage.

TECH FIG 1 • **A.** Clinical photograph of an exposed distal femur with the creation of a long cortical window with evidence of infected soft tissue within the intramedullary canal. **B.** Fluoroscopic image showing debridement of the femur intramedullary canal with a curette. **C.** Photograph of sequestra removed during debridement of the distal femur. **D.** Photograph of cement antibiotic beads placed into the bone defect after debridement of chronic osteomyelitis. **E.** Postoperative AP and lateral (**F**) radiographs of the distal femur after debridement, placement of antibiotic beads, and stabilization of the defect.

PEARLS AND PITFALLS

Hip and knee

- In the setting of infection, consider aspirating adjacent joints to ensure there is no associated septic arthritis.
- Surgical stabilization should be robust enough to allow joint passive

	range of motion during recovery.
Debridement	■ Retained hardware likely has a bacterial biofilm. Efforts should be made to remove all foreign bodies during the debridement.
Tumor	■ Bone tumors can look like bone infection. If there is any uncertainty, a biopsy should be performed before debridement.
Bacteria	■ Some microbiology labs can run polymerase chain reaction (PCR) to identify microbial DNA.
Antibiotic nail	■ Bone defects can be supported with an antibiotic intramedullary nail. Inject a chest tube with cement mixed with antibiotics and let dry with a guide wire inserted into the cement. A small injection nozzle is often needed. Once dry, bend the guide wire at the top to facilitate removal of the nail. Bone must be reamed to a diameter 1.5 mm larger than the diameter of the chest tube.

POSTOPERATIVE CARE

- Dressings can be removed in 48 hours and the patient may shower with soap and water.
- Encourage early range of motion of surrounding joints to avoid stiffness.
- Intravenous medications are tailored to operative cultures and are determined in consultation with infectious disease specialists. Cultures may not grow because many patients receive antibiotic therapy before debridement and some bacteria require special media.
- Patients with infection are monitored clinically and with serial lab studies (ESR and CRP). After antibiotics are complete, the patient is observed for a few weeks for signs of recurrent infection. If there are no concerns, management of the bone defect can ensue. Many physicians will perform intraoperative frozen section studies assessing the number of neutrophils per high-powered field at any subsequent surgeries. It is wise to maintain suspicion of infection.
- Persistent or recurrent infection starts the process over again.

OUTCOMES

- Coagulase-negative *Staphylococcus* and *Staphylococcus aureus* are the most common causes of bacterial osteomyelitis.³
- Age (60 years and older) and diabetes are risk factors for osteomyelitis.⁴
- The most common cause of persistent infection is inadequate debridement.⁵ Often times, the site of inadequate debridement is the intramedullary canal.

COMPLICATIONS

- The bone that does not heal after debridement, stabilization, and possible antibiotic therapy should trigger additional workup to examine host factors, poor vascularity of tissues, presence of unidentified metabolic conditions, and possible persistent or new infection.
- Nonhealing bone should also consider the need for more stability (hypertrophic nonunion) or more biology (atrophic nonunion).

Reconstruction of Femur

CHAPTER

Vishwanath R. Chegireddy, Michael J. A. Klebuc, and Anthony Echo

DEFINITION

- Femoral shaft bone defects usually result from tumor resection, traumatic loss, chronic osteomyelitis, congenital skeletal defects, failed allografts, or infected nonunions.^{1,2}
- Extensive resection of long bone can lead to large intercalary osseous defects necessitating reconstruction, which was traditionally achieved with allografts or allograft prosthetic composites. These allografts were associated with high rates of complications, including joint instability, fracture of the allograft, and infection of the allograft.³
- Vascularized bone flaps are essential for successful bone reconstruction due to their ability to incorporate into the recipient site and provide early bone consolidation while maintaining stability of the appendicular skeletal structure. Owing to its independent blood supply, such a flap is well incorporated into the recipient bone despite compromised surrounding tissue from previous surgery or radiation therapy.
- The advantage of vascularized bone flap over nonvascularized bone grafts is the intrinsic ability to integrate into the recipient bone similar to standard fracture healing instead of creeping substitution.
- The fibula is an ideal vascularized bone flap for femur reconstruction due to its ease of access for harvest while preserving the stability of the proximal and distal tibial-fibular syndesmosis despite segmental resection. It has a negligible influence on knee and ankle joint stability without compromising weight-bearing ability or function of the lower extremity.
- The vascularized fibular flap undergoes hypertrophy overtime in response to continuous pressure load, which translates to remarkable long-term

durability.^{4–6}

ANATOMY

- The femur is the longest and strongest bone in the body and is subject to large amounts of axial loading as well as significant rotational angular stresses.
- The fibula is a long and thin cortical bone with a small medullary component. In adults, the width of the fibula is 1.5 to 2 cm with a length of 35 cm of which approximately 25 cm of the fibular diaphysis can be harvested for free tissue transfer.
- Vascular supply to the diaphysis of the fibula is via a dominant nutrient endosteal artery and minor musculoperiosteal branches from the peroneal artery and veins. These vessels run parallel to the fibula and course between the flexor hallucis longus (FHL) and tibialis posterior muscle group.
- The dominant nutrient artery branches 6 to 14 cm from the peroneal artery bifurcation and enters the fibula posterior to the interosseous membrane. It then courses into the nutrient foramen located in the middle third of the diaphysis and further divides into an ascending and descending branch.
- Musculoperiosteal vessels are derived from the peroneal artery and travel within the posterolateral septum, through the FHL and tibialis posterior muscle, giving segmental rise to four to eight branches that supply the muscles in the anterior compartment, soleus muscle, and lateral leg skin territory. The majority of the periosteal branches are located in the middle third of the fibula (**FIG 1**).
- Soft tissue defect coverage is achieved with a skin paddle supplied by perforators traversing through the posterior crural septum with the majority concentrating at the proximal and distal ends of the fibula. These fasciocutaneous perforators supply a skin paddle up to 10 × 20 cm in size.⁷

PATIENT HISTORY AND PHYSICAL FINDINGS

- Detailed preoperative evaluation is required for patients undergoing extensive long bone resection and intercalary bone defect reconstruction.
- A thorough medical history should be obtained to evaluate the peroneal artery for free fibula graft. Pertinent history includes trauma, deep venous thrombosis, peripheral vascular disease, lymphedema, or venous insufficiency. Patients with peripheral vascular disease may not be a candidate for surgery.
- Physical exam should include an evaluation of knee and ankle joints for range of motion and laxity, and a foot Allen test with a Doppler probe to assess

dorsalis pedis and posterior tibial arteries.

- Peronea arteria magna is a congenital variant of the arterial inflow to the foot, which affects about 1% to 8% of the population, where both the anterior and posterior tibial arteries are hypoplastic or absent with the peroneal artery serving as the single arterial supply below the knee.
- Patients with an abnormal vascular exam or a history of trauma to the affected extremity will need additional preoperative imaging such as an arteriogram, computed tomography angiogram (CTA), duplex ultrasound, or magnetic resonance angiography (MRA) to identify atherosclerotic occlusive disease or congenital anomalies.

FIG 1 • A. Cross-sectional anatomy of four compartments at midtibial level. **B.** Vascular supply to the lower extremity.

IMAGING

- Preoperative imaging of both the recipient and donor sites should include an evaluation of:
- Recipient site:

- The extent of bone resection, length and diameter of the intercalary defect, and potential soft tissue defect (**FIG 2**). This allows the surgeon to determine the extent of the tumor burden, traumatic bone loss, or chronic osteomyelitis and plan for reconstructive options.
- Donor site:
 - Evaluate vascular supply with Doppler ultrasound (anterior tibial, posterior tibial, and dorsalis pedis arteries), and exclude any fibular deformities.
 - Angiogram to look for vessel patency and flow to the foot.

FIG 2 • **A.** Anterior and lateral (**B**) preoperative MRIs showing a right midfemur chondroblastoma. **C.** Plain radiograph of the right femur showing chondroblastoma.

SURGICAL MANAGEMENT

Preoperative Planning

- Free fibula bone graft can be transferred with a generous skin paddle and adjacent muscles such as soleus, peroneal muscles, or FHL.
- Either right or left leg can be used as a donor for fibula flap. The left side is preferable in most patients because it is the less dominant leg and used less frequently while driving a vehicle. However, thoughtful planning of vessel orientation in the recipient site should be considered, when deciding upon laterality.
- Prior to incision, anatomical landmarks including the head of the fibula, lateral malleolus, and anterior and posterior border of the fibula are marked. The posterior border of the fibula correlates with the posterior intermuscular

septum encasing the vascular supply to the skin paddle (**FIG 3**).

- Intraoperative Doppler probe is used to identify perforator vessels to design the skin paddle centered over the posterior crural septum. Sometimes, the perforators pass through the FHL and/or soleus muscles and lie posterior to the septum.
- Area of fibula bone resection is marked with superior margin 4 cm below the head of the fibula and inferiorly 6 cm above the lateral malleolus. By preserving the proximal fibula, the stability of the knee is maintained without disrupting the attachment of the tibia to the fibula, fibular collateral ligament to the head of the fibula, and biceps femoris muscle. Also, the common peroneal nerve courses inferior to the head of the fibula, and identifying this location can prevent injury during dissection.

Positioning

- Positioning can allow two surgical teams to work simultaneously, if the contralateral fibula flap is used (**FIG 4**):
 - The patient is placed in the supine position on the operative table with the donor side knee flexed 90 degrees. A roll is placed under the ipsilateral hip to internally rotate the pelvic girdle and keep the hip and knee flexed.
 - A heel stop can be placed on the operative room table to help knee at 90 degrees, when harvesting in the supine position.
- The patient can also be placed in lateral decubitus position if donor and recipient site is in the same limb:
 - A bean bag can help keep the patient in the lateral position.
 - All pressure points should be carefully padded and protected.

FIG 3 • Intraoperative marking of anatomical landmarks for an ipsilateral fibula harvest in the lateral decubitus position: head of the fibula, lateral malleolus, and anteroposterior fibular border.

FIG 4 • If the contralateral fibula flap is desired, the patient can be placed in a supine position, which allows two teams to work simultaneously for recipient preparation and donor site harvest.

Approach

- Plastic surgeons and orthopedic surgical team will need to work together to coordinate resection of the affected femur segment and reconstruction of the subsequent intercalary defect. Preservation of potential recipient vessels is of the utmost importance.

- Reconstruction of long femoral intercalary defects with vascularized fibula alone is not sufficient due to inadequate stability and fragility of the bone to tolerate early weight bearing. The Capanna method is ideal in this scenario, using a femoral allograft as a peripheral shell and telescoping the free fibula graft through the allograft segment.⁷
- Reconstruction of smaller intercalary defects up to 13 cm can be achieved with double-barrelled fibular flap, keeping the arterial blood supply intact while performing an osteotomy in the fibula flap.
- Initial exposure by the plastic surgeon serves to protect the recipient vessels for microvascular anastomosis at a later point. Although any artery or vein of adequate caliber can be utilized as the recipient vessel, the descending branch of the lateral femoral circumflex artery and vein is the preferred vessel because of its location.
- If extensive soft tissue defect is anticipated due to trauma or tumor/chronic osteomyelitis resection, then a skin paddle can be harvested with the fibular flap by sharing the same vascular pedicle, which helps with early detection of flap compromise and provides tension-free skin closure of recipient site.

TECHNIQUES

■ Free Fibula Flap

- After the bone tumor or chronic osteomyelitis resection by the orthopedic surgical team, the dimensions of the intercalary bone defect are measured (**TECH FIG 1A**).
- Prior to flap harvest, a sterile tourniquet is placed on the midthigh while avoiding compression over the fibular head and common peroneal nerve.
- By tracing the anatomical landmarks, a midlateral vertical incision is made over the fibula, and skin flaps are elevated at the level of the fascia.

elevated at the level of the fascia.

TECH FIG 1 • A. Right femoral intercalary defect remaining after the tumor resection. **B.** Exposure of peroneus longus and soleus at the midtibial level. **C.** Dissection around the fibula and lateral muscle

compartment. Dissection proceeds proximally to identify and protect the superficial peroneal nerve. **D.** Dissection anterior to the fibula through the anterior intermuscular septum and protecting the deep peroneal nerve and anterior tibial vessels. **E.** After the distal fibula osteotomy, the peroneal vessels located between FHL and tibialis posterior muscle groups should be ligated distally. **F.** Adequate fibula length is freed, and proximal osteotomy is performed carefully while protecting the pedicle vessels. **G.** Isolated fibula graft with intact peroneal vessels.

- Dissection is carried through the investing fascia of the lateral compartment, anterior to the posterior intermuscular septum (**TECH FIG 1B–D**):
 - Care should be taken to preserve fasciocutaneous perforators traveling through the posterior intermuscular septum if a skin island is needed for osteocutaneous flap.
- During proximal dissection, identify and preserve the common peroneal nerve traversing around the head of the fibula to become the superficial peroneal nerve.
- The peroneal muscles are dissected off the anterior surface of the fibula and reflected anteriorly to expose the anterior intermuscular septum. The septum is incised to gain access to the anterior compartment and reflect extensor digitorum and hallucis muscles to identify and preserve anterior tibial vessels and deep peroneal nerve.
- The interosseous membrane is incised to enter the deep posterior compartment, and the peroneal vessels are located between tibialis posterior and flexor hallucis longus (FHL) muscles.
- After adequate length of the fibula is marked for reconstruction, towel clamps are used to apply lateral traction on the proximal and distal fibula while osteotomizing with an oscillating saw or Gigli saw. If possible, a strip of periosteum overlying the osteotomy site should be included to overlap the osteotomy sites at the recipient site.
- Prior to performing osteotomy, a microvascular clamp can be applied to the peroneal artery distal to the osteotomy site to ensure adequate supply to the

foot and then divided (**TECH FIG 1E**):

- The vascular pedicle is dissected starting distally and carried proximally up to the origin of tibioperoneal trunk and ligated with approximately 2 to 6 cm of pedicle length.
- Next, the peroneal vessels are identified proximally and distally, and dissection is propagated circumferentially around the fibula while staying medial to the vessels using a large right-angle clamp. The vascular pedicle should be maintained during dissection.
- After the fibula graft is fully mobilized with the pedicle (**TECH FIG 1F,G**), the tourniquet is released. One should see robust arterial inflow and venous outflow and healthy back bleeding from both the periosteum and intramedullary canal.
- An osteomuscular flap can also be harvested in similar fashion to include soleus and FHL muscles. This can aid in filling the dead space in patients with extensive soft tissue defect.
- If the distal osteotomy is close to lateral malleolus, a screw fixation to the tibia can be utilized to prevent valgus deformity and ankle instability, which is more important in a pediatric patient.

■ Capanna Method

- The Capanna technique combines a vascularized fibula graft with massive allograft to reconstruct large defects of the femur to provide structurally competent reconstruction with vascular perfusion and osteogenic capability to achieve lower rates of infection, fracture, and nonunion.⁸
- The free fibula graft can be harvested in similar fashion mentioned earlier:
 - The allograft is cut to match the resected defect, and the medullary canal of the allograft is enlarged with a reamer to create a space for fibula graft (**TECH FIG 2A**).
 - A bur is used to create a window in the allograft to accommodate the vascular pedicle without external compression (**TECH FIG 2B**).

TECH FIG 2 • A. In the Capanna technique, the allograft is cut to match the femur defect size, and the fibula is telescoped into the intramedullary canal of the allograft. Care should be taken to accommodate the vascular pedicle. **B.** The Capanna technique using a femoral allograft. **C.** Microvascular anastomosis between the recipient vessels (descending branch of the lateral femoral circumflex artery and vein) and the flap vessels (peroneal artery and vein).

- The fibula is telescoped into the intramedullary canal of the allograft and delivered into the recipient site. This is anchored to the femur proximally and distally with compression plates and screws. During this step, care is taken to prevent any damage to the nutrient vessel.
- Standard microvascular anastomosis is performed between the recipient

vessels and peroneal artery and accompanying venae comitantes (**TECH FIG 2C**):

- Additionally, several fat grafts can be placed around the pedicle in an effort to prevent compression.
- A well-padded posterior leg splint is applied to keep the foot in extension to prevent an equinus deformity.

■ Double Barrel Fibula Technique

- This technique can be useful for reconstruction of smaller femur defect without the use of an allograft:
 - Larger defects will not be able to be reconstructed with a single fibula in a double-barreled fashion; both fibulas would need to be harvested which is not usually recommended.
- The fibula graft is harvested in similar fashion as described previously. This technique provides a graft that doubles the cross-sectional area of the flap but only requires single arterial and venous anastomosis (**TECH FIG 3**).
- At the site of the proposed osteotomy, the vascular pedicle is carefully elevated off the bone flap in the subperiosteal plane with an elevator over a segment of 2 to 3 cm, which will allow a malleable retractor to be placed to protect the pedicle.
- The graft is osteotomized at the midpoint, with care taken to preserve the peroneal vessels.

TECH FIG 3 • In the double-barrelled fibula repair, free fibula is harvested with the peroneal vessels intact. The graft is then osteotomized at the midpoint and folded.

PEARLS AND PITFALLS

Flap inset

- The goal is to maximize bone-to-bone contact between the recipient bone ends and fibula flap.
- Opposition and stability can be achieved by making wedges, steps, or another method that articulates the bone ends together. Creating adequate opposition helps with bone healing while minimizing the number of screws placed into the fibula flap for fixation.

Vascular pedicle

- Any fixation needs to consider the vascular pedicle of the flap. The plate should not be placed over the vascular pedicle. In some cases, the screws placed within the bone flap may need to be unicortical. The plastic surgeon should be actively involved with the fixation and inset of the flap.

Vascular variations

- Peronea arteria magna is a congenital variant of the arterial inflow to the foot, where both the anterior and posterior tibial arteries are hypoplastic or absent with the peroneal artery serving as the single arterial supply below the knee.

Injury to common peroneal nerve

- The nerve courses inferior to the head of the fibula and should be identified during proximal dissection to prevent injury.

Careful dissection of skin perforators

- Preserve the posterior intermuscular septum, which carries perforators to the skin paddle.

POSTOPERATIVE CARE

- Monitor donor site for signs and symptoms of vascular insufficiency or compartment syndrome.
- Assess the drains daily and remove if output is less than 20 to 30 cc/day.
- Monitor the flap postoperatively with clinical exam and using Doppler probe every hour for the first 24 hours. Flap monitoring should continue until discharge to check microanastomotic patency and skin island perfusion.
- An internal implantable Doppler can be utilized to monitor a bone flap without a skin paddle.
- No ambulation for 2 weeks postoperatively. Afterward, start with partial weight bearing with crutches until full weight bearing when bone union is achieved.
- If an osteocutaneous flap used for reconstruction fails due to vessel thrombosis, the skin island can be debrided or allowed to heal secondarily. The bone graft can remain in place, and hyperbaric oxygen therapy can be utilized to increase the chance of bone revascularization.

OUTCOMES

- Limb functionality varies depending on trauma, tumor, or infectious etiology.
- Patient counseling is crucial: numerous revision procedures (8.7 per patient)⁹ common for best results
- 64% of lower extremity flap complications resolve conservatively; 36% require additional bone grafting or flap revisions.¹⁰
- Full bone healing: 86% of patients
- Ambulation: all patients (100%) at an average 9.5⁹ to 14.3 months¹¹

- Joint stiffness (40%) and pain (18%) are frequent.⁹
- Return to work: 63.5% of patients with primarily salvaged limbs¹²

COMPLICATIONS

- General complications:
 - Wound infection (9.6%–23.2%)^{9,11,13,14}
 - Bleeding (6.7%)⁶
 - Delayed wound healing or dehiscence (10.0%)⁶
 - Cosmetically unpleasant scar
- Recipient site:
 - Flap failure (3.8%–5.8%)^{12,14} due to compromised flap perfusion (eg, anastomotic thrombosis)
 - Minor necrotic areas (11.5%)¹⁴ due to temporary interruptions of the vascular supply
 - Bone nonunion (15.5%–31.0%)^{12,13}
 - Osteomyelitis (8.6%–17.3%)^{12,13}
 - Revision surgery and need bone for grafting
 - Amputation as ultima ratio (3.9%–7.3%)^{12,13}
- Donor site:
 - Knee/ankle instability with secondary pseudoarthrosis (2.0%)⁹
- Prevention: sparing 6 cm at the proximal and 6 cm at the distal end of the fibula in order not to violate the connective structures:
 - Inability to flex the great toe due to extensive dissection of FLH
 - Loss of sensation of peroneal nerve (10.0%)⁹
 - Skin graft failure after donor site closure
- Because of the improvements of microsurgical training and techniques, the use of autologous tissue for lower extremity reconstructions is continuously increasing and offers lower complication rates compared to allografts.⁶

ACKNOWLEDGMENTS

Thank you to D. Zavlin, MD, and Michael J. A. Klebuc, MD, of Houston Methodist Hospital and Weill Cornell Medicine, Houston, Texas, for their help in preparing this chapter.

39 Soft Tissue Coverage of the Thigh—Pedicled Rectus Flap

CHAPTER

Brock Lanier and Alex Wong

DEFINITION

- Soft tissue defects of the thigh can involve critical anatomy including the neurovascular structures of the femoral triangle (i.e. common femoral artery, common femoral vein, and femoral nerve) and/or bone.
- Prior infection, radiation, trauma, tumor resection, or other pathologies can render local or pedicled flaps from the thigh unusable for reconstruction. In such scenarios the pedicled rectus flap is a reliable workhorse for thigh defects.
- The rectus flap is very versatile. It can be used as a pedicled muscle or myocutaneous flap. The available flap dimensions can range from a small segment of muscle to a large flap incorporating an extended skin component.¹

ANATOMY

- The rectus abdominis muscle spans the vertical length of the abdominal wall. It originates from the pubis, inserts at the fifth to seventh costal cartilage, and is situated in pairs along the paramedian axis of its anterior wall. It is a Mathes and Nahai type III muscle with two codominant vascular pedicles: the superior epigastric artery and the inferior epigastric artery (**FIG 1**).
- In order to use the pedicled rectus flap for thigh reconstruction, the superior epigastric artery is transected and the flap is rotated maintaining the blood supply from the inferior epigastric artery.
- Perforating branches from the inferior epigastric artery are concentrated around the umbilicus. As such, the periumbilical area should be incorporated into the design of any myocutaneous flap's skin paddle.
- If the periumbilical perforators to the skin are utilized, an almost infinite

number of skin paddle designs are possible. Large (*size*) skin paddles can be transposed to the thigh defect if needed.²

FIG 1 • VRAM clinical anatomy. The rectus abdominis muscle originates from the pubis and inserts at the fifth to seventh costal cartilage. It has codominant vascular pedicles: the superior epigastric artery and the inferior epigastric artery. The VRAM skin paddle must include periumbilical skin perforators.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most soft tissue defects involving the thigh are associated with either trauma or cancer.
- Focused examinations of the abdomen and lower extremity should be performed:
 - The abdominal examination should evaluate for previous surgical scars, the

presence of abdominal wall hernias, and skin laxity if a myocutaneous flap is being considered:

- Transverse midabdominal laparotomy scars indicate that the rectus abdominis was likely transected.
- Low transverse scars associated with prior cesarean sections may or may not have violated the inferior epigastric pedicle.
- Check the neurovascular status of the lower extremities. Trauma or surgery, particularly vascular surgery, involving the external iliac artery or common femoral artery, may have compromised the inferior epigastric pedicle.

IMAGING

- Imaging is not mandatory but can be considered if the patient's physical exam is concerning regarding the integrity of the inferior epigastric artery.
- CT angiography can assess the pedicle and can concurrently evaluate the abdominal wall for occult hernias and other pathologies.
- MR angiography and ultrasonography are other modalities that can also be considered.

NONOPERATIVE MANAGEMENT

- Nonoperative treatment of soft tissue defects of the proximal thigh is limited, especially when critical structures of the femoral triangle or osseous structures of the lateral thigh are exposed.
- Temporary coverage using vacuum-assisted wound care devices can be considered depending on the contents of the wound.

SURGICAL MANAGEMENT

- Surgical management decisions include timing (immediate vs delayed reconstruction) and choice of the flap.
- Flap options include local pedicled flaps of the thigh such as the anterolateral thigh flap, tensor fascia lata flap, gracilis flap, and sartorius flap.
- Free flaps are also an option if appropriate regional options do not exist.

TECHNIQUES

■ Flap Design

- The size and depth of the soft tissue defect should be defined following tumor resection or wound debridement.
- Critical landmarks include the symphysis pubis and the anterior superior iliac spine (ASIS), which defines the inguinal ligament.
 - The origin of the inferior epigastric artery is at the halfway point of the distance between the symphysis pubis and the ASIS.
- The paramedian location of the rectus abdominis muscle is marked.
- If desired, a template of the defect can be constructed (e.g., using wrapping paper from sterile gloves) to facilitate creation of the design of the skin paddle. It is suggested that the length of the muscle and the size of the skin paddle be slightly larger than the defect.
- The donor site of muscle flaps will almost always close primarily.
 - The donor site of skin paddle of a myocutaneous flap should be assessed during flap design. A pinch test can ensure that the donor site will be able to close primarily.
- In pedicled flaps such as the rectus abdominis, the pivot of the flap about its vascular pedicle should be considered during flap design (**TECH FIG 1**).
 - Typically, the flap will rotate externally to reach a lateral thigh defect and internally to reach a medial thigh defect. A sterile towel or laparotomy pad can be used to simulate the arc of rotation of the flap about its pivot point to ensure adequate length of the flap during flap design.

TECH FIG 1 • Lateral view of the abdomen and right thigh, demonstrating proximal anterolateral thigh full-thickness defect with exposed femur. The extended vertical rectus myocutaneous (eVRAM) flap has been

marked incorporating the flap's periumbilical perforators into its design.

■ Flap Harvest

- For a muscle flap without skin island, the approach may be via a paramedian incision directly over the muscle or a low transverse abdominoplasty incision.
 - Once the anterior rectus sheath is exposed, it is entered sharply in the middle of the muscle and reflected medially and laterally to expose the muscle.
 - For smaller defects of the thigh, a segment of the muscle can be harvested, leaving the remaining muscle supplied by the superior epigastric artery.
- For a myocutaneous flap (**TECH FIG 2A**), the skin paddle must be in continuity with the anterior rectus sheath to incorporate perforating vessels.
 - At the medial and lateral surface, the fat and skin can be elevated 1 to 3 cm off of the anterior sheath to allow for the donor site to be closed directly.
- To complete harvest, the muscle is circumferentially dissected off of the posterior rectus sheath (**TECH FIG 2B**).
 - Below the arcuate line, the posterior sheath is thin because it consists only of transversalis fascia.
 - Neurovascular bundles associated with intercostal nerves are controlled with either suture ties or clips.
 - The inferior epigastric pedicle is identified at the inferolateral aspect of the muscle approximately 4 cm cranial to the origin.
- The flap's pedicle can be dissected back to its external iliac origin to maximize the arc of rotation.
 - Care should be taken not to exert excessive tension or pressure on the pedicle during the dissection.
- The cranial aspect of the muscle is transected at the costal margin, taking particular attention to identifying the superior epigastric artery.
 - The caudal aspect of the muscle can also be divided from the pubic origin for additional length.

TECH FIG 2 • A. Examples of skin paddle designs of VRAM and extended VRAM. **B.** Dissected extended VRAM in situ at the donor site.

■ Flap Inset and Completion

- According to the location of the soft tissue defect, the flap can be rotated or tunneled to the defect (**TECH FIG 3A**).
 - With the flap in situ at the recipient site, its vascular status should be assessed before inset.
 - The pedicle can be checked to ensure there is minimal twisting and no acute turns compromising flow.
 - For myocutaneous flaps, the skin paddle's cutaneous Doppler signal sites should be examined and can be marked with ink or small suture (e.g., 5-0 polypropylene) to facilitate postoperative monitoring.
- The flap is inset in layers using suture and/or staples. A skin graft can be applied if appropriate (**TECH FIG 3B**).
- The anterior rectus sheath donor site is repaired directly with sutures (e.g.,

no. 1 PDS).

- When a skin paddle is incorporated into the flap, mesh is usually required to minimize tension on the repair.³

TECH FIG 3 • A. Rotation of VRAM flap demonstrates that it can reach past midthigh. Final intraoperative lateral view appearance of the abdomen and right thigh with the eVRAM donor site closed primarily and the flap inset after de-epithelization and tunneled through the subcutaneous space.

Artery preservation

- In the setting of large soft tissue defects involving the proximal thigh, it is essential to ensure that the origin of the inferior epigastric artery has been preserved.
- Radical resections involving the ipsilateral common femoral artery or external iliac artery will likely compromise the flap's pedicle. The need for vascular reconstruction of these vessels should alert the reconstructive surgeon.

Flap design

- The flap can be trimmed and customized to a smaller size during inset. It cannot be enlarged once it has been dissected.
- For this reason, a larger flap is recommended (longer rectus and/or larger skin paddle). Consider a 20% larger design than what is suggested by the initial measurements of the soft tissue defect.

POSTOPERATIVE CARE

- The abdominal donor site can be dressed with a sterile occlusive dressing (e.g., gauze, adhesive tape, or topical liquid bonding product).
- The dressing for the flap depends on the type of the flap (muscle with or without skin graft, skin paddle) and preference of the surgeon.
- Pedicled flaps to the proximal thigh are at risk with early postoperative motion. A short period of immobilization, especially for flaps with overlaying skin grafts, should be considered.
- Flap checks examining the color, turgor, temperature, and/or Doppler signal should be performed in accordance with institutional standards. Many protocols call for hourly flap checks during postoperative day 1, every 2 hours on postoperative day 2, and every 4 to 6 hours thereafter.

OUTCOMES

- The pedicled rectus abdominis flap has a constant blood supply, making it a safe and reliable option for small to large soft tissue defects of the proximal thigh (**FIG 2**).

COMPLICATIONS

- Obesity, smoking, uncontrolled diabetes, and prior abdominal surgery are factors that have been associated with an increased risk of complication.⁴
- Intraoperative vascular complications related to twisting or kinking of the pedicle during inset
- Acute venous insufficiency is rare but can occur in patients with a dominant superficial venous system. If this is encountered, then the flap can be returned

to its native position, and its inset can be postponed for a few days allowing for the delay phenomenon to occur.

- Partial flap necrosis may occur at the distal aspect of the skin island in myocutaneous flaps.⁵
- Postoperative hematoma or seroma⁵
- Donor site bulge or hernia (12%)⁵

FIG 2 • Result 1 year postoperatively, demonstrating the postoperative appearance of the healed eVRAM donor site and flap.

40 Soft Tissue Coverage of Thigh—Free Flaps

CHAPTER

Ulrich Kneser and Thomas Kremer

DEFINITION

- Soft tissue defects of the thigh requiring free flap reconstruction are rare, because of a sufficient soft tissue envelope that frequently allows other reconstructive options such as split-thickness skin grafting, local random pattern, or pedicled flaps.
- Exposure of functional structures such as neurovascular bundles, tendons, or bone may require reconstruction using free microvascular tissue transfer.

ANATOMY

- Anatomy of the thigh is characterized by a sufficient number of strong muscles:
 - Anterior:
 - The quadriceps muscle (medial, lateral, and vastus intermedius muscle as well as rectus femoris muscle)
 - The sartorius muscle
 - Medial:
 - The adductor muscles (gracilis, adductor magnus, adductor longus, adductor brevis, and pectineus muscle)
 - Posterior:
 - Biceps femoris muscle
 - Semitendinosus muscle
 - Semimembranosus muscle
- Perfusion of the thigh is maintained by the femoral artery and its branches:
 - Profunda femoris artery (with medial circumflex and lateralis artery)

- Descending genicular artery
- Popliteal artery
- Peripheral branches of the inferior gluteal artery for the proximal dorsum
- Major nerves of the thigh are:
 - The femoral nerve (quadriceps, sartorius, and pectineus muscle)
 - Obturator nerve (adductor muscles)
 - Sciatic nerve (posterior muscles of the thigh)
- Venous drainage of the thigh is provided by deep veins and the saphenous vein.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Defects at the thigh may result from trauma, infection, or oncologic resection. Each of these entities should be evaluated and requires special focus during patient examination.
- Patients with traumatic soft tissue defects of the thigh should be asked for the mechanism of injury. This may help to identify the true extent of the defect and concomitant trauma consequences.
- Infections of the thigh should be evaluated for dynamics, systemic consequences (eg, fever, fatigue), pain, prior antibiotic treatment, as well as potential causes and infectious portals of entry.
- The major goal in patients after oncologic resection is to evaluate prognosis, prior treatment, and adjuvant treatment options, since this information strongly influences therapeutic as well as reconstructive choices.
- Additional important factors influencing reconstruction are patients' demands: patients who were ambulating normally prior treatment may require more extensive reconstructive attempts than patients who are chair- or even bed-bound.
- Inspection of the thigh in patients suffering from soft tissue loss should assess the extent and depth of the defect as well as exposed functional structures. Additionally, the surroundings of the defect should be carefully evaluated: scarring, tension, and former incisions should be noted. Prior radiation therapy may lead to wound healing disturbances and subsequent postoperative morbidity and should therefore be taken into account.
- When free flap reconstruction is required, potential donor vessels should be evaluated. The distance from these vessels to the most distant part of the defect should be measured and significantly influences flap choices. In some patient, even more invasive strategies such as arteriovenous loops or bypasses may be

necessary.

- Patients should be asked for varicosity or prior venous surgery (such as venous stripping or bypass surgery).

IMAGING

- Photographs of the defect should be performed including the complete thigh as well as detailed pictures focusing on the defect.
- Conventional x-rays of the femur in two perpendicular views (anteroposterior and lateral) may show concomitant fractures or nonunions in traumatic cases, osteomyelitis after infection, or oncologic osseous lesions in oncologic patients.
- Magnetic resonance imaging and computed tomography may reveal the real extent of the defect or sequelae of infection of the bone as well as soft tissue. However, both options should not postpone onset of treatment in special patients such as cases with necrotizing infections.
- Radiologic examination of donor vessels is required in patients prior to microsurgery for thigh defects. MRI or CT angiographies are sufficient in most cases. The advantage of conventional angiographies in these patients is that endoluminal interventions are possible, if necessary.
- Doppler or duplex ultrasound is indicated to evaluate the superficial venous system and for venous mapping if vein grafts may be required.

SURGICAL MANAGEMENT

- Indications for free flap reconstruction at the thigh are relatively rare. Most cases can be managed using local random pattern or pedicled flaps as well as split-thickness skin grafting. However, extensive defects with exposure of functional structures such as bone, neurovascular bundles, or tendons may require free tissue transfer.
- Another reason for microsurgical flap transplantation is radiation therapy. Tissues from distant donor sites that are not radiated may improve the healing capacity of irradiated wound beds. This is especially important because soft tissue sarcoma of the limbs most commonly occur at the thigh.¹ Here, defect reconstruction using free flaps can even be indicated when primary wound closure would be possible with tension. In these patients, complications rates can be reduced when reconstruction with nonradiated flaps is applied.
- Any reconstructive attempt should only be started when wounds are sufficiently debrided. No signs of infection or devitalized tissue should be

present.

- In some cases, vacuum-assisted closure (VAC) therapy can be performed to prepare wounds for soft tissue reconstruction.

Preoperative Planning

- Different parameters influence the choice for various reconstructive options:
 - The aim of reconstruction (eg, palliative vs curative intention, limb salvage vs major amputation; ability to walk or just to sit)
 - Structures or functions requiring reconstruction, extent of the defect (eg, soft tissue loss, bone damage, muscle function, nerve injury)
 - Perfusion of the wound bed (eg, in patients with peripheral arterial disease, after radiation therapy)
 - The patients' individual needs and compliance as well as concomitant diseases
 - Donor site morbidity
 - Adjuvant therapy options or further surgery
- Another important information is the distance from potential donor vessels to the most distant part of the defect. If this distance is too long, the risk of partial flap loss ("where you need it most") is increased. In these cases, arteriovenous loops or vessel interpositional grafts should be considered.
- Patients with atherosclerosis should be evaluated by angiography and should be presented to vascular surgeons or interventional radiologists prior to surgery.
- If multidisciplinary approaches are required (eg, osseous internal fixation, soft tissue reconstruction and/or vascular surgical interventions), a detailed preoperative discussion is required. The sequence and extent of different surgical steps, postoperative care, and operative strategy has to be considered. Here, interdisciplinary extremity boards similar to oncologic tumor boards have been shown to be very efficient.

Positioning

- Patient positioning depends on donor vessels, flap choice, as well as additional surgical interventions (eg, osteosyntheses, vascular surgery, harvest of vein grafts).
- Supine positioning allows:
 - Common flaps: anterolateral thigh flap, gracilis flaps, rectus abdominis myocutaneous flaps, tensor fascia lata flaps, vastus lateralis flaps, lateral arm

flap, forearm flaps

- Donor vessels: femoral artery and vein in the groin and adductors canal
- Lateral decubitus position (**FIG 1A,B**):
 - Common flaps: flaps from the subscapular system
 - Donor vessels: femoral artery and vein in adductor canal
- In some patients, it is not possible to perform the complete procedure in one position (eg, when internal osseous fixation is required). Here, intraoperative repositioning may be necessary.

Approach

- The surgical approach to defects at the thigh is defined by defect localization as well as extent and cannot be discussed here in detail.
- Recipient vessels at the thigh predominantly are the femoral vessels. These can best be approached in the groin and the adductors canal.
- In patients with unfavorable defect localization, microvascular anastomoses can be performed to arteriovenous loops (that can be performed in the same procedure or separately in prior procedures) or interpositional vein grafts.
- If different approaches to the defect, vessels, and bone have to be combined, the surgeons should carefully discuss operative incisions in advance to prevent skin malperfusion.

FIG 1 • The lateral decubitus position of patients allows exposure of the thigh and femoral vessels, if the contralateral leg is placed backward. **A.** Care has to be taken for the upper arm that has to be prevented from any compression to prevent compartment syndromes in lengthy procedures. **B.** Flaps from the subscapular

system can easily be harvested.

TECHNIQUES

Video p7-c040

■ Approach to the Groin

- The femoral artery and vein can easily be identified in the groin (**TECH FIG 1**). These vessels arise from the external iliac artery and course under the inguinal ligament into the thigh. Here, the artery can usually be found by palpation. The femoral vein is located medial to the artery, whereas the femoral nerve courses laterally.
- The course of the vessels across the thigh is between the vastus medialis muscle (laterally) and the adductor muscles. Distally, the sartorius muscle lies superficial to the vessels.
- Major arterial branches in the groin are the deep femoral artery, the superficial epigastric, and the circumflex iliac artery. The saphenous vein can likewise be identified in the groin.
- The skin incision is performed distal to the inguinal ligament over the vessels that were previously identified by palpation or Doppler probe. During subcutaneous preparation, the saphenous vein should be identified and preserved.
- Because the femoral vessels lie on the muscles in the groin, these structures

can easily be dissected. For safety reasons, the major branches should be identified (especially the deep femoral artery) and secured using vessels loops.

- After dissection of the femoral artery and vein over several centimeters, an adventitiectomy should be performed to prepare the vessels for anastomosis that is usually performed in an end-to-side fashion.

TECH FIG 1 • A. The femoral vessels can be exposed in the groin. Here, the femoral vein (A) is visualized caudal to the inguinal ligament. Dissection was performed to the entry of the saphenous vein. (B) Here, the saphenous vein is pulled cranially (left) to form an arteriovenous loop through an end-to-side anastomosis (C) to the femoral artery (D) in the groin. **B.** Illustration of the femoral vessels in the groin.

■ Approach to the Adductor Canal

- The anatomical borders of the adductor canal are:
 - Dorsally: adductor longus muscle (**TECH FIG 2A**)
 - Ventrally: vastoadductor membrane between the tendons of the vastus

medialis and adductor longus muscles (see **TECH FIG 2A**)

- Medially: adductor magnus muscle
- Laterally: vastus medialis muscle
- The femoral vein is located under (“deep”) the femoral artery.
- Additional structures in the adductor canal are the saphenous nerve and the descending genicular artery.
- The approach to the femoral artery and vein is possible in supine as well as lateral decubitus position.
- The skin incision is performed at the medial thigh (**TECH FIG 2B**). During subcutaneous dissection, the saphenous vein can be found and prepared for anastomosis.
- After incision of the fascia of the thigh, the descending genicular artery can be identified (**TECH FIG 2C**). This structure can be used as a guide into the adductor canal, and the femoral artery and vein can easily be found. Both vessels are then dissected (**TECH FIG 2D**).
- Care has to be taken to preserve the femoral vein behind (deep) to the femoral artery. Several arterial and venous branches arise from the femoral vessels in the adductor canals. Some of these generally seem to be sufficient for anastomosis. However, the authors recommend ignoring these vessels because complication rates are significantly higher when compared to direct end-to-side anastomoses to the “big” femoral vessels.

TECH FIG 2 • A. Illustration of the adductor canal. **B.** The adductor canal is exposed through a medial skin incision. **C.** After subcutaneous dissection and incision of the fascia, the descending genicular artery can be identified (*arrow*). **D.** This structure guides into the adductor canal, and the femoral artery can be identified and dissected as well as the femoral vein. Here, the saphenous vein is anastomosed to the femoral artery to create an arteriovenous loop (*arrow*).

■ Dissection of the Saphenous Vein

- The saphenous vein collects the blood of the dorsum of the foot and courses superficially at the lower leg. Around the knee, it courses dorsal to the medial

femoral condyle before it runs anteriorly at the thigh and penetrates the fascia in the groin where it enters the femoral vein (**TECH FIG 3**).

- The entire course of the saphenous vein is epifascially.
- During dissection, numerous branches can be identified. These should be ligated with sutures rather than vessel clips, because the latter often prove to be insufficient and postoperative bleeding occurs. This is especially important, when parts of the vein are inserted into the arterial system in arteriovenous loops, since vessel clips frequently fail to withstand arterial pressure.
- If the saphenous vein is exposed to arterial pressure, it significantly lengthens. This effect has to be considered when arteriovenous loops are performed. Here, the arterial part of the loop should be planned slightly shorter than the venous side.

TECH FIG 3 • The saphenous vein collects the blood

of the dorsum of the foot and courses superficially at the lower leg. Around the knee, it courses dorsal to the medial femoral condyle before it runs anteriorly at the thigh and penetrates the fascia in the groin where it enters the femoral vein.

■ Flap and Anastomosis

- If muscle flaps are performed, these should be harvested together with skin islands to allow postoperative supervision of perfusion. These skin islands can be dissected based on one perforator and can therefore be removed after 7 to 10 days just by ligation of the perforator and to not require a second procedure.
- After flap harvest (**TECH FIG 4A**), the flap is provisionally secured to the thigh, and the recipient vessels are approximated to the femoral vessels.
- End-to-side anastomoses should be preferred over end-to-end anastomoses to side branches for the arterial system, because the flow is higher and consecutive complication rates are reduced. Venous anastomosis is routinely performed in end-to-end fashion to side branches of the (**TECH FIG 4B–E**) femoral vein using coupler devices or standard suture. In cases of insufficient venous branches, direct end-to-side anastomosis to the femoral vein or end-to-end anastomosis to the saphenous vein is applicable.
- After the anastomoses are finished, it is useful to secure the anastomotic site using fibrin glue to prevent postoperative repositioning and subsequent vessel kinking.
- Adequate perfusion of the flap is either checked by capillary refill or by brisk capillary bleeding from the flap margins.

TECH FIG 4 • A. A combined latissimus (A) and parascapular (B) flap was harvested to reconstruct an extensive traumatic defect after a motor bike accident (C). The vascular pedicle was dissected to the subscapular artery and vein **B.** End-to-side anastomosis (*arrow*) was performed of the subscapular artery to the femoral artery. **C.** Venous anastomosis (*arrow*) was likewise done to the femoral vein. **D.** An extensive traumatic defect at the thigh with exposed femur required reconstruction using free tissue transfer because the femoral vessels were exposed (*arrow*). **E.** After anastomosis to the femoral vessels.

■ Flap Inset, Skin Grafting

- After flap reperfusion, manipulation to the anastomotic side should be avoided for some minutes. During this period, anastomotic flow is established and minor anastomotic bleeding terminates.
- Flap inset is performed temporarily using suture clips. The anastomotic site and flap pedicle are then checked for optimal positioning before the flap is definitely sutured to the defect. Skin-to-skin closure is preferred in fasciocutaneous flaps, whereas muscle flaps are fixed under the defect margins that should be elevated. Here, running sutures using absorbable monofilament material are preferred over nonresorbable sutures.
- Muscle flaps should be covered using split-thickness skin grafts (**TECH FIG 5**). In these cases, it can be useful to provide vacuum-assisted closure therapy to the skin-grafted area (using low pressures such as 75 mm Hg) to allow optimal wound healing.
- Split-thickness skin grafting can be performed under monitor skin islands already, if these are harvested based on perforators.
- Care has to be taken to prevent any compression to the anastomosis or flap pedicle when wound dressings are applied.

TECH FIG 5 • A,B. Flap inset was performed, and the latissimus flap as well as the proximal thigh musculature were skin grafted (A, proximal thigh muscles; B, parascapular flap; C, latissimus dorsi flap with split-thickness skin grafts).

PEARLS AND PITFALLS

Preoperative planning	■ A detailed analysis of the defect is necessary prior to surgery to identify every structure that needs to be reconstructed. ■ For flap choice, the distance from the anastomotic site to the most distant part of the defect has to be considered. ■ The bulk of the flap has to be considered, when skin-to-skin closure is attempted.
Arterial disease	■ If the patient suffers from peripheral arterial disease or varicosity, a vascular surgeon or interventional radiologist should be involved in the treatment team.
Patients' needs	■ The patients' needs have to be evaluated prior to surgery. The reconstructive aim significantly varies if the patient is ambulating normally or if he is chair- or bed-bound. ■ Palliative surgery vs curative attempts in oncologic patients.
Anastomosis	■ End-to-side anastomoses to the femoral vessels are preferred over end-to-end anastomoses to side branches, because blood flow is greater and complication rates are reduced.
Postoperative care	■ Flap perfusion has to be monitored on a regular base for the first postoperative days. ■ Monitoring is possible clinically in fasciocutaneous flaps, or monitor skin islands of muscle flaps. The latter can be harvested based on a perforator to allow removal without additional surgery.

POSTOPERATIVE CARE

- Postoperative positioning of the patient can be crucial. Compression of the pedicle or flap has to be avoided. Here, postoperative positioning has to be discussed with the patient preoperatively. This increases the patients' understanding and compliance.
- External fixators can be helpful to allow adequate postoperative positioning.
- Postoperative anticoagulation is part of an ongoing debate.² In general, less intervention is preferred over aggressive anticoagulation. The authors only prescribe low molecular weight heparin for thromboembolic prophylaxis. Higher doses or intravenous heparin are only applied in bypass free flaps or after revision surgery. If patients develop thrombocytosis or arterial clots, acetylsalicylic acid can be useful.
- Flap perfusion has to be monitored on a regular base (hourly) to allow

immediate revision surgery if arterial inflow or venous drainage is compromised.

- After 5 to 7 days, the flap should be exposed to gravity (so-called dangling procedure), and the patients should be mobilized.³
- Physical therapy has to be applied from the first postoperative days.
- Compression garments are usually required to avoid bulky flaps and scars as well as contractures. Scar massage is beneficial in most patients.
- Physical therapy and rehabilitation have to be planned in most patients. However, these are mostly defined as the individual defect and rarely depend on the microsurgical procedure itself (**FIG 2**).

OUTCOMES

- Outcomes after free flap surgery to thigh defects mostly depend on the underlying condition rather than on the microsurgical procedure itself.
- Outcomes in traumatic patients mainly depend on wound healing, osseous healing, and long-term function due to scarring or post-traumatic arthritis.
- Prognosis in oncologic patients depends on the tumor itself and is determined by size, location, tumor biology, immunology, and distant metastases.

FIG 2 • Results after 2 months with uneventful wound healing (medial view **(A)**, lateral view **(B)**).

- Infectious control is of utmost importance in consecutive patients. Here, flap perfusion is as important as postoperative antibiotic treatment that can be required for long periods, when osteomyelitis is evident.

COMPLICATIONS

- Flap failure rates vary significantly depending on defect causes and localization. Failure rates between 1% and 10% are described internationally.⁴

- Other complications include wound infection, incomplete healing or ongoing infection, as well as partial flap loss. The latter can be as detrimental as a complete flap loss and should therefore be prevented if possible. Here, flap dimensions should not be extended as much as possible. If large defects have to be reconstructed, flaps should be combined, or microsurgical effort has to be increased for maximum safety (eg, inclusion of multiple perforators with in-flap anastomoses, use of arteriovenous loops, bypass free flaps, combined or chimeric flaps).

41 Nerve Repair and Reconstruction—Sciatic Nerve and Femoral Nerve

CHAPTER

Gabrielle B. Davis and Catherine Curtin

Sciatic Nerve

DEFINITION

- The sciatic nerve is the largest peripheral nerve in the body.
- Its role is critical for lower extremity protective sensation and ambulation.
- Sciatic nerve injury in the setting of lower extremity trauma was historically an indication for amputation.
- Recent advancements in microsurgical techniques have led to improved outcomes and viability of the extremity.

ANATOMY

- The origin of the sciatic nerve is from the ventral divisions of L4, L5, S1, S2, and S3.
- The confluence of nerve fibers joins in the pelvis and exits via the greater sciatic foramen and below the piriformis muscle (**FIG 1**).
- In the buttocks, the sciatic nerve is located posterior to the gluteus maximus muscle and anterior to the superior gemellus, obturator internus, inferior gemellus, and quadratus femoris.
- It courses inferiorly, midway between the greater trochanter and the ischial tuberosity.
- In the posterior thigh, it travels deep to the long head of the biceps femoris.
- There are two distinct divisions of the sciatic nerve traveling within the same

sheath, the peroneal and tibial divisions.

- In the upper thigh, the tibial division gives off branches to all of the hamstring muscles (semitendinosus, semimembranosus, biceps femoris) except for the short head of the biceps femoris (**FIG 2**).
- The peroneal nerve distribution innervates the short head of the biceps femoris and the ischial portion of the adductor magnus muscle.
- The two divisions will separate completely at the level of the popliteal fossa.
- The posterior tibial nerve continues its course posteriorly to innervate the muscles in the posterior leg compartment.
- The common peroneal nerve will course laterally around the head of the fibula to innervate the muscles of the anterior and lateral compartments.
- The inferior gluteal artery provides majority of the blood supply to the sciatic nerve.

FIG 1 • Course of the sciatic nerve as it exits the pelvis

below the piriformis muscle.

Innervation/Function

- In the upper thigh, the sciatic nerve is responsible for motor function to the hamstrings muscles, which allow for flexion at the knee.
- The common peroneal and tibial branches are responsible for all of the motor function below the knee.
- It provides cutaneous sensory innervation to the posterior thigh.
- Its terminal branches provide sensation to the lateral aspect of the knee, lateral lower leg, and the dorsal and plantar surfaces of the foot.

Mechanisms of Injury

- The sciatic nerve is at risk for entrapment as it passes through the sciatic notch, especially in the setting of pelvic fractures.
- Traumatic injuries, particularly in penetrating trauma, can occur at any level with variable grades of severity.
- Iatrogenic injuries are not uncommon and result from pelvic and hip surgery, as well as injection site injuries.
- Revisional hip surgeries and patients with developmental dysplasia are at higher risk.¹
- Direct compression neuropathy is rare but has been described in comatose patients during prolonged anesthesia or long periods of sitting on a hard surface.² Piriformis syndrome is a compressive neuropathy of the sciatic nerve as it travels underneath the piriformis muscle.

FIG 2 • A,B. The sciatic nerve path in the posterior thigh as it divides in the popliteal fossa into the peroneal and tibial divisions.

PATIENT HISTORY AND PHYSICAL EXAM

- Detailed history and physical examination must be obtained prior to the decision for operative management.
- Documentation of muscle strength using the Medical Research Council

(MRC) scale and sensory deficits by two-point discrimination along the cutaneous distribution of the nerve.

- The extent of sensory deficit can also be measured by the “ten-test for sensation.” The patient grades the level of sensation to touch on the injured side using a scale from 1 to 10. This number is compared to the level of sensation to similar touch on the uninjured side.
- Physical manifestations will be dependent on the level of injury, extent of each nerve division involved, and if it is a partial or complete injury.
- High injury can lead to significant morbidity, as buttock-level sciatic nerve lesions will result dysfunction of knee flexion, foot extension, flexion, inversion, eversion, and all movement of the toes.
- Sensory losses of variable degrees result in the posterior thigh and the entire foot and lower leg except for the medial aspect of the lower leg, which is supplied by the saphenous nerve.
- Injuries below the level of the hamstring can allow ambulation with an intact femoral nerve as the patient can have active flexion, extension, and locking of the knee.
- Patients with piriformis syndrome complain of buttock pain and numbness. This can also result in pain radiating down the leg and thigh “sciatica.”
- Patients with piriformis syndrome may have a history of buttock trauma, and symptoms are exacerbated by prolonged sitting or activities resulting in adduction and internal rotation of the leg.
- On physical exam, the proximal sciatic is tested by asking the patient to flex the knee against resistance with the lower leg extended.
- The peroneal branch is tested by assessing foot extension, eversion, and abduction of the toes against resistance.
- The tibial branch is tested by assessing foot plantar flexion and flexion of the toes against resistance.
- To test for piriformis syndrome, the “AIF” maneuver should be performed. The AIF maneuver consists of adduction, internal rotation, and flexion of the hip.
- Pain on AIF maneuver is diagnostic for piriformis syndrome.

IMAGING

- Detailed physical exam detailing sensory and motor deficits will help delineate the level of injury.

- Nerve conduction studies can also assist with localization of the injury.
- Of note, electromyography (EMG) has limited utility in the acute setting, as muscles may not demonstrate signs of denervation for several weeks.
- For piriformis syndrome, imaging may demonstrate hypertrophy of the piriformis muscle, anomalous vessels, or bands around the muscle.

FIG 3 • MRI neurogram showing bright fascicles of the sciatic nerve.

- Magnetic resonance (MR) neurogram is an emerging technique in which edema or inflammatory changes around a nerve could help identify location of injury (**FIG 3**).

NONOPERATIVE MANAGEMENT

- If the injury is closed or due to compression, a trial of conservative management should first be attempted.
- Physical therapy should be initiated early, focusing on ambulation with bracing and orthotics.
- Pain management for relief of neuropathic pain includes pharmacologic modalities and therapy for desensitization.

- If no significant return of function is noted by 3 months, then surgical exploration is warranted.
- Unrelenting pain could indicate neuroma formation and may warrant surgical exploration even if signs of spontaneous recovery are evident.
- Treatment for piriformis syndrome is typically conservative including stretching of the muscle and image-guided steroid injections.
- If conservative treatment fails, then surgical release of the piriformis can be considered.

FIG 4 • Patient prepared for surgery of distal sciatic injury after knee dislocation. *Arrow marks the area of nonadvancing Tinel.* Note the needles in place for baseline motor responses during the intraoperative nerve monitoring.

SURGICAL MANAGEMENT

- Concern for laceration to one or both branches as demonstrated by significant motor or sensory deficits warrant early operative exploration.³
- Intraoperative electrophysiologic studies can serve as a guide to determine the area of injury for compression, stretch, or blunt injuries that have not spontaneously recovered (**FIG 4**).
- If nerve action potentials are detected across the injured site, external neurolysis should be performed.
- Nerve repair or reconstruction should be performed in the setting of a nerve not in continuity or intraoperative nerve testing that finds no recovery across

the zone of injury.

- Primary repair should always be attempted if there is not significant tension on the repair.
- If primary repair without tension cannot be performed, reconstruction should be performed with nerve grafting.
- Neuropathic pain is a common concern. The use of antineuropathic pain medications should be part of the patient's multimodal treatment.

TECHNIQUES

■ Upper Sciatic Nerve: Hip and Buttock Pathology

- The patient should be placed in the prone position.
- A bump can be placed beneath the pelvis to provide flexion at the hips.
- The contralateral lower extremity should also be prepped and draped in the event a sural nerve graft is required for repair.
- A curvilinear incision is made starting at the posterior superior iliac spine, traveling laterally to the greater trochanter, and inferiorly to the gluteal crease.
- The dissection is carried down to the level of the gluteus maximus muscle.
- The superior and lateral aspect of the gluteus maximus muscle is released from the iliotibial tract.
- A 2- to 3-cm cuff of the muscle is left to the superolateral attachment to facilitate closure.
- An avascular plane below the gluteal maximus muscle should be developed by retracting the muscle medially to expose the sciatic nerve.
- Careful hemostasis using bipolar electrocautery is critical for good visualization.
- Care must be taken not to injure the hamstring branches as they typically run superior and medial to the main sciatic trunk.
- The gluteal neurovascular structures travel along with the sciatic nerve, and care must be taken to preserve these vessels.
- In some cases, the piriformis muscle will need to be detached from the femur laterally and retracted medially for improved exposure of the nerve at the sciatic notch.

■ Lower Sciatic Exposure: Thigh Pathology

- The patient is placed in the prone position.
- An incision is made over the suspected level of injury.
- Tourniquet may not be feasible, given proximal lesion and need for nerve monitoring; therefore, preinject suspected site prior to prepping with bupivacaine with epinephrine.
- Dissection can be carried down to the popliteal fossa for full exposure of the nerve depending on the level of injury (**TECH FIG 1A**).
- A plane is developed between the biceps femoris and the semitendinosus muscle.
- Careful hemostasis using bipolar electrocautery is critical for good visualization.
- The sciatic nerve can be exposed running deep to the biceps femoris (**TECH FIG 1B**).
- The sheath should be divided exposing the two divisions of the nerve for full inspection of injury.
- Further isolation of the nerve should be performed under an operating microscope, with adequate exposure of the nerve proximal and distal to the lesion.
- The nerve should be resected to healthy nerve fascicles.

TECH FIG 1 • A. Nerve-to-nerve monitoring of the sciatic nerve to tibial nerve to assess for neuroma in continuity. The *black arrow* represents the division becoming the tibial nerve, the *blue arrow* the peroneal

nerve. **B.** Lacerated sciatic nerve exposed in the posterior thigh. Note the large caliber of this nerve.

■ Primary Nerve Coaptation

- Nerve repair should be performed via end-to-end epineural coaptation with 9-0 monofilament permanent sutures.
 - Fibrin sealant can also be used to reapproximate and seal nerve ends.
 - A sural nerve graft can be interposed between the two ends if primary repair is not possible.
 - The peroneal and tibial components should be repaired separately aligning their respective fascicles.
-

PEARLS AND PITFALLS

Hemostasis

- Preinject incision with bupivacaine with epinephrine.
- A solution of 1 amp of epinephrine diluted in 100 cc of saline can be used to moisten a gauze, which is then dabbed in the wound to help with visualization.

Technique

- In the thigh, there are numerous branches of the sciatic nerve to the hamstring muscles, and care must be taken not to injure these branches during dissection.

Intraoperative monitoring

- Communication between neurology and anesthesia teams is critical to ensure that patient does not receive medications that will hinder intraoperative monitoring.
- The machines for the sequential compression device and warming blankets can cause background that interferes with intraoperative monitoring.
- Do not use tourniquet if planning intraoperative monitoring as ischemia of the nerve can result in neuropraxia.

Diagnosis

- Must determine sciatic nerve injury vs pelvic plexus trauma, as repair of the latter may be contraindicated.

POSTOPERATIVE CARE

- If there is concern for tension across the nerve repair, range of motion exercises should wait for at least 3 weeks.
- Physical therapy should be initiated early focusing on ambulation with the use of braces and orthotics.
- Early therapy for desensitization and scar management are useful to minimize postoperative pain.
- If pain is severe, a multidisciplinary approach with pain management, psychology, and therapy should be initiated.

OUTCOMES

- Factors associated with worse outcomes include delay in repair of more than 4 months, length of nerve defect, and division of nerve involved.⁴
- One of the largest series evaluating outcomes of civilian sciatic nerve injuries was performed at Louisiana State University Health Science Center:⁵
 - They evaluated outcomes of 353 patients with buttock-level and thigh-level sciatic nerve injuries over a 24-year period.
 - Mechanisms of injury included injection injuries, hip surgeries, fracture dislocations, blunt ant penetration trauma, and compression.
 - Patients with partial nerve deficits without severe pain or with significant spontaneous recovery were treated with conservative management and achieved good recovery of motor and sensory function.
 - Patients with detectable nerve action potentials intraoperatively only underwent neurolysis.
 - Overall, they found thigh-level sciatic nerve injuries achieved better outcomes than buttock-level injuries (Table 1).
 - In addition, for peroneal nerve injuries, both primary repair and nerve grafting had worse outcomes in comparison to tibial nerve injuries.
 - It is postulated that worse outcomes for peroneal nerve injuries results from less robust blood supply and connective tissue padding between fascicles compared to the tibial nerve.^{6,7}

COMPLICATIONS

- Neuropathic pain. There is a higher incidence of neuropathic pain with delayed repairs.⁶
- Development of complex regional pain syndrome (CRPS)
- Neuroma
- Rupture

Table 1 Percent of Patients Who Achieved At Least a Medical Research Council strength of at least 3

Level of Injury	All patients	Suture Repair	Nerve Graft Repair
Buttock	87%	73	62
Thigh	96%	93	80
Tibial	71%	30	24
Peroneal	79%	69	45

Kim DH, et al. Management and outcomes in 353 surgically treated sciatic nerve lesions. J Neurosurg. 2004;101(1):8-17.

Femoral Nerve

DEFINITION

- Femoral nerve injuries are more common than sciatic nerve injuries.
- Most injuries are iatrogenic, resulting from abdominal and pelvic surgeries.
- In general, femoral nerve injuries have a better prognosis than other lower extremity nerve injuries.
- Most patients typically maintain the ability to ambulate with the use of orthotics.
- Early identification and treatment are critical for prevention of muscle atrophy and the need for long-term rehabilitation.

ANATOMY

- The femoral nerve forms in the pelvis from the ventral rami of L2, L3, and L4 spinal roots (see **TECH FIG 1B**).
- The nerve travels in the retroperitoneum, anterior to the psoas muscle and medial to the iliacus.
- It enters the thigh deep to the inguinal ligament and travels through the femoral triangle, which is bordered superiorly by the inguinal ligament, laterally by the sartorius, and medially by the adductor longus muscle.
- In the femoral triangle, it runs lateral to the femoral artery.
- Approximately 1 to 4 cm distal to the inguinal ligament, it divides into the

anterior and posterior branches (**FIG 5**).

- The lateral circumflex femoral artery typically runs between the two divisions.⁸
- The anterior division provides motor innervation to the sartorius muscle and sensory innervation to the anterior and medial upper thigh.
- The posterior division provides motor innervation to the quadriceps muscles.

FIG 5 • Course of the femoral nerve in the anterior thigh.

- Its terminal division is the saphenous nerve, which runs with the greater saphenous vein and provides sensory innervation to the medial lower leg and foot.
- The blood supply to the femoral nerve is derived from the iliolumbar artery in

the pelvis and the deep circumflex iliac artery and lateral circumflex femoral artery in the thigh.

Innervation/Function

- In the pelvis, it provides motor innervation of the psoas and the iliacus muscles, which contributes to flexion at the hip.
- It also gives off a branch in the pelvis or upper thigh to innervate the pectineus muscle that aids in adduction of the hip.⁸
- In the thigh, it provides motor function to musculature of the anterior compartment including the quadriceps (rectus femoris, vastus lateralis, vastus medialis, and vastus intermedius) and the sartorius muscle.
- The quadriceps functions to extend the knee, and the sartorius contributes in flexion, abduction and lateral rotation of the hip, as well as flexion of the knee.
- The femoral nerve does not provide any motor innervation below the knee.
- Sensory innervation of the femoral nerve includes the anterior thigh.
- Its terminal branch, the saphenous nerve, provides sensory innervation to the medial knee and medial lower leg, as well as the medial aspect of the foot.

PATHOGENESIS

- Majority of the published femoral nerve injuries are the result of iatrogenic injury from abdominal and pelvic procedures, primarily from compression by self-retaining retractors.⁸
- The saphenous nerve especially the infrapatellar branch can be injured during knee surgery. This can result in chronic pain after total knee arthroplasty.⁹
- At the inguinal ligament, the femoral nerve can become compressed particularly with flexion, abduction, and external rotation of the legs, such as in lithotomy position.
- Inadvertent injury during arterial cannulation for cardiovascular procedures has also been described.
- Retroperitoneal hematomas, pelvic lymphadenopathy, and colon or rectal malignancies can lead to femoral nerve compression in the pelvis.
- Femoral nerve stretch injuries can also be caused by hip hyperextension in dancers or yoga instructors.
- Ischemic injuries can lead to nerve devascularization, such as in aortic or iliac surgeries.

PATIENT HISTORY AND PHYSICAL EXAM

- Motor and sensory exam techniques are same as sciatic nerve.
- Evaluation of a patient with femoral nerve injury employs the same principles as for sciatic nerve injury.
- Injury to the intrapelvic femoral nerve results in weakness with hip flexion, knee extension, and an absent or diminished patellar reflex.
- Sensory deficits can include numbness, paresthesias, or hyperesthesia along anteromedial thigh and medial lower leg.
- Hip flexion should be tested by supporting and flexing the knee while requesting the patient to flex hip against resistance.
- Loss of quadriceps function can result in knee hyperextension if there is a functional tensor fascia lata or gracilis muscle.
- On reflex examination, the patient will have loss of knee jerk.
- The saphenous nerve can be compressed at the adductor hiatus: tenderness, Tinel, and positive scratch collapse at the adductor hiatus can help identify this.

IMAGING

- Similar evaluation as for sciatic nerve injury

NONOPERATIVE MANAGEMENT

- Contusions, compression, traction, or partial injuries are initially managed with conservative strategies to determine the amount of spontaneous recovery.
- Early ambulation is encouraged with the use of knee or knee to ankle orthotics for weakness of quadriceps muscles.
- All patients should participate in aggressive physical therapy to prevent muscle atrophy and the development of deep venous thrombosis.
- Joints can also be maintained supple by dynamic and static splinting to prevent contractures, in the event early ambulation cannot be performed.
- If there is no recovery of motor or sensory function within 3 months, surgical intervention is warranted.

SURGICAL MANAGEMENT

- Complete lacerations require early surgical exploration and repair.
- If the patient's medical condition is stable, neurorrhaphy should be performed within the first 3 to 7 days of injury.
- Primary repair should be attempted when possible, and autologous nerve grafts from the sural nerves is an alternative.
- For high femoral nerve palsies, a transfer of the obturator nerve has been

described. These transfers have demonstrated good functional outcomes; however, there are limited data.¹⁰

TECHNIQUES

■ Retroperitoneal Femoral Nerve Exposure: Pelvic Pathology

- The patient should be placed in the supine position.
- Surgical bumps should be placed under the hip to elevate the affected side.
- Dissection is carried down to the level of the external and internal oblique muscles.
- The muscle-splitting technique is utilized to separate the muscles in the direction of their fibers.
- The transversalis fascia is opened and the peritoneum retracted superiorly away from the retroperitoneal fat.
- The retroperitoneal fat is carefully mobilized for exposure of the femoral nerve, just lateral to the femoral artery.
- The iliac vessels and ureter will be coursing medially to the nerve.
- Dissection can be carried superiorly to the iliopsoas muscle for high exposure of the nerve.
- Care should be taken not to injure the lateral femoral cutaneous nerve and ilioinguinal or genitofemoral nerves.
- The inguinal ligament can be divided if needed to facilitate exposure.

■ Lower Femoral Nerve Exposure: Thigh-Level Pathology

- The patient is positioned supine with the knee flexed 30 to 45 degrees.
- The femoral artery is palpated midway between the anterior superior iliac spine and the pubic symphysis.
- A longitudinal incision is made lateral to the femoral artery or the midaspect of the inguinal ligament.
- The incision is carried inferiorly to the midthigh, following the course of the

femoral nerve.

■ Painful Saphenous Neuroma

- The patient has had nerve blocked preoperatively, has had at least a 70% pain reduction, and is comfortable with the trade of decreased sensation for decreased pain.
- Identify area of pain and look for nerve proximally (**TECH FIG 2A**).
- If discrete nerve injury is identified, resect neuroma and reconstruct defect with allograft (**TECH FIG 2B**).
- If there is any question as to the extent of the zone of injury, it is advised to resect nerve proximally so it does not cross a joint and bury the end of the nerve within the muscle under no tension.

TECH FIG 2 • A. Patient with a painful neuroma in the saphenous nerve distribution after a laceration: *circle* denotes painful area and *dotted line* area of decreased sensation. **B.** Neuroma resected and defect reconstructed with nerve allograft.

■ Nerve Repair

- The nerve is identified using the existing wounds or the approaches described above.
- The nerve can be directly coapted if a tension-free repair is possible.
- If there is tension on the repair, a bridging nerve graft is required.
- Nerve coaptation is done using microsurgical technique.

- Use 9-0 suture with minimal amount of sutures placed.
- Fibrin sealants can be used to seal the repair site and to hold cabled nerve grafts together.
- Repairs are protected for 3 weeks with splints/braces to limit mobility at adjacent joints.

PEARLS AND PITFALLS

Pathogenesis	■ Similar to sciatic nerve injury. ■ The femoral nerve travels with the femoral artery and femoral vein, and concomitant vascular injuries are common.
Surgical management	■ Vascular injury must be performed prior to nerve repair.

POSTOPERATIVE CARE

- Physical therapy should be initiated early focusing on ambulation with the use of braces and orthotics.
- Therapy should also focus on desensitization and scar management.

OUTCOMES

- There is a paucity of robust studies on outcomes of femoral nerve repairs.
- For the majority of compression, stretch, or partial lacerations, good outcomes in motor function have been reported; however, most patients have residual sensory deficits.^{8,11}
- The Louisiana State University Health Science Center series published outcomes of 119 operative repairs of femoral nerve injuries over a 32-year period.¹¹
- Mechanisms of injuries included iatrogenic, hip or pelvic fractures, gunshot wounds, and lacerations.
- They demonstrated good functional recovery regardless of mechanism of injury, level of the lesion, or primary vs nerve grafting.
- In addition, they reported that the majority of patients who had neurolysis regained almost complete function, for both thigh- and pelvic-level lesions.

- They concluded that femoral nerve injuries overall have a good prognosis, consistent in other smaller series.⁶

COMPLICATIONS

- Chronic pain
- Development of complex regional pain syndrome
- Neuroma
- Rupture

42 Keystone and Related Perforator Flaps

CHAPTER

Michael W. Findlay

DEFINITION

- Keystone flaps encompass a group of related fasciocutaneous flaps first devised by Behan that share a common geometric design (a keystone shape similar to the keystone of stone arches) but can vary in the following ways:¹
 - Blood supply (perforator vs direct vs neurovascular vs composite)
 - Degree of islandization (complete vs incomplete, cutaneous or fasciocutaneous)
 - Method of transfer into the defect (advancement, transposition, combination)
 - Whether used alone or along with another keystone flap on the opposite side of the defect (double opposing keystone flaps).
- The classification of keystone flaps is based on the method of transfer and the number of keystone flaps involved (**FIG 1**).

ANATOMY

- Keystone flaps close defects by transferring fasciocutaneous tissue from an adjacent donor site to the defect while maximizing use of cutaneous arteries, superficial and deep venous drainage, and lymphatics without being defined by a specific form of the transfer (eg, transposition vs rotation).
- Human skin is well supplied with perforators and direct vessels for supply of keystone flaps with established patterns of cutaneous supply in the limbs (longitudinally oriented septocutaneous and musculocutaneous perforators), the trunk (segmental perforators with intercommunications in well-defined intermuscular planes), and the head and neck (profuse cutaneous supply dominated by direct cutaneous vessels in the head and perforators and direct vessels in the neck).²

- Conjoint supply to flaps refers to the incorporation of both cutaneous vessels and neurovascular supply within the flap (eg, incorporation of saphenous or sural nerves and their vasa nervorum) so as to augment blood supply. Codevelopment of arteries and nerves during development result in conjoint flaps that have a very strong axial blood supply that improves their robustness. An additional benefit is that blood supply from the vasa nervorum can be significant in some areas (eg, posterior thigh), further contributing to flap vascularity.
- Certain sites do not contain cutaneous perforators (eg, pretibial border, scalp) and hence represent problem areas for keystone flap elevation. Keystone flaps can be raised either side of the pretibial border for mobilization of tissue over a pretibial defect, but cannot reliably be designed directly over the pretibial skin as the basis for its blood supply due to the lack of direct cutaneous perforators.
- Superficial and deep venous drainage can be incorporated in most keystone perforator flaps through preservation of deep venous system along with arterial perforators and the subcutaneous veins by blunt dissection of subcutaneous tissues and islandization of the underlying fascia (if necessary) via the use of scissors through small windows in the subcutaneous tissue. Superficial veins are often numerous, and some may need to be divided to permit sufficient mobilization, but their division is performed sequentially, stopping once sufficient mobilization is achieved.

FIG 1 • Basic design and types of keystone flaps. **A.** An ellipse is formed as though the defect is to be closed primarily. Then, a keystone flap is designed beside it with sharp dissection undertaken through the skin and deep fascia. **B.** V-Y closure is performed at the flap margins during flap advancement. **C.** A skin graft may be used for closure of the secondary defect. **D.** Double opposing keystone flaps may be used on either side of

the defect. **E.** This is particularly useful for midline defects, for which the flaps can form mirror images. **F.** Yin-yang variant of double opposing keystone flaps. **G.** When one end of the keystone flap is transposed to fill a defect, skin grafting of the secondary defect may be necessary.

- The longitudinal orientation of fascial planes in many areas of the body (eg, limbs, paraspinous region) predispose to a longitudinal orientation for keystone flaps (slightly oblique orientations may help in limbs; see below), with the most appropriate mobilization of longitudinal keystone flaps being in a transverse direction. That is, the longitudinal orientation of the paraspinous musculature makes medial and lateral movement of keystone flaps relatively easy to cover central back defects, whereas the fibrous attachments between the skin and underlying spinous processes make superior or inferior movement problematic.
- Where there is circumferential limitation for flap mobilization and direct closure of the secondary defect (eg, distal limbs), orienting keystone flaps oblique to the long-axis provides an oblique (longer) circumference, thereby maximizing available donor tissue for closure.
- Placement of incisions in relaxed skin tension lines where possible is very helpful. The keystone shape is one that naturally hides well. Caution should be exercised in selection of any island flap in patients prone to abnormal scarring (eg, hypertrophic/keloid scarring). Partial flap islandization is a good option where feasible in such individuals or in patients very sensitive about the scar burden.
- Undermining and skeletonization of the perforator/direct vessel pedicle to the flap can be undertaken but is unnecessary in the vast majority of cases, and therefore, only the division of structures felt absolutely necessary for elevation, mobilization, and inset of the specific keystone flap are undertaken, thereby ensuring both surgical efficiency and safety.
- The design and flexibility in the blood supply, venous drainage, and mobilization of the keystone flap make it readily suitable for application in most areas of the body with local variation to optimize the outcome in specific areas.

PATIENT HISTORY AND PHYSICAL FINDINGS

- An understanding of the etiology of the defect to be reconstructed and relevant patient factors (health, comorbidities, activity levels, mobility, nutrition) help direct the most appropriate form of reconstruction in any potential flap case.
- As with all forms of flap reconstruction, particular interest should be focused on removal of the causative factor (eg, cancer, infection), identification and optimization of locoregional blood flow, selection of the best possible flap based on the needs of the defect and locoregionally available tissue, and optimization of the patient in the perioperative period.
- Any past history of conditions that affect local blood flow and wound healing should be elicited and mitigated where possible (eg, irradiation, peripheral vascular disease (micro and/or macroangiopathy), diabetes mellitus, smoking, and previous surgery/trauma).
- Examination findings of note include quality of surrounding donor sites for skin and tissue quality (including presence of radiotherapy tattoos, scars, fibrosis).

IMAGING

- The vast majority of patients do not require preoperative imaging or the use of intraoperative Doppler ultrasound to achieve reliable and timely reconstruction using the keystone flap or its variants as long as normal design principles are followed (see **FIG 1**).
- Computed tomography, angiography, and similar imaging modalities are the most useful to answer what direct or perforating vessels are available to the locoregional tissues, and delayed views can show the venous drainage to the area of interest.
- Fluorescence microscopy is invaluable for pre- and intraoperative imaging of the perforators and direct vessels to the skin but is rarely indicated for keystone flap elevation and has anaphylaxis as a risk factor.
- Imaging can be of use where previous surgery or trauma may have damaged the normal blood supply of the donor skin, or if there is significant arterial disease, and therefore, the selection of the most appropriate local vessels is necessary to ensure success.

NONOPERATIVE MANAGEMENT

- As with any fasciocutaneous defect, careful consideration should be given to the potential of the defect to be closed directly (under physiologic tension and

utilizing biological and mechanical creep as tolerated) or healed by secondary intention.

- The progression to flap reconstruction is considered where these options are either not possible or lead to unacceptable risks/complications.

SURGICAL MANAGEMENT

- Keystone flap reconstruction is reliable as long as a sequence of steps is undertaken in which the primary goal is sufficient mobilization of the flap to close the recipient and donor sites, while preserving as much arterial input, venous output, and lymphatic drainage as possible.
- No additional maneuvers are undertaken once recipient and donor-site closure can be achieved.
- If further mobilization of tissues is needed, then the flap can be fully islandized where the cutaneous vessels have been followed back through deep fascia and or freed where they exit muscles to facilitate mobilization; however, one must be cautious not to damaging perforating vessels as this can lead to tissue ischemia and necrosis.

Preoperative Planning

- The defect is assessed for its suitability for fasciocutaneous reconstruction, with a consideration of locally available tissue, including potential vascular pedicles, as the basis for the flap.
 - Keystone flaps can be performed in irradiated tissue¹ or even in the setting of lymphedema,² but caution should be exercised with flap planning in these settings so as to ensure adequate perforators/direct vessels and avoid unnecessary tension across suture lines.
- Where primary closure is unachievable, consider a keystone design and determine the form of mobilization that will work best to close the defect and match the local tissue shape (eg, transposition flaps are best for convex surfaces and advancements are best for flat surfaces).
 - There are circumferential limitations in the limbs (where the defect size represents over 30% to 40% of the circumference of the limb), as these defects may require grafting of the secondary defect or an alternate form of reconstruction.
- Defects are marked out as though they are to be closed directly as part of an elliptical excision/closure, and keystone flaps can be designed on one or both sides of the ellipse with the best side (or sides) chosen based upon local tissue

availability, suitability of local vessels, and the needs of the defect.

- The ellipse does not need to be excised. It simply gives a guide to the best orientation for the flaps.
- It is good practice to mark every excision or defect as though it will be closed by a keystone flap and then perform one if the defect cannot be closed primarily (if indicated). This maximizes experience with keystone planning.

Positioning

- Patient positioning is entirely dependent upon the ensuring easy access to the operative site. This is usually supine or lateral with circumferential draping in the limbs.
- Prone positioning is most useful for midline defects of the back that require bilateral keystone flaps.

Approach

- The design and mobilization of keystone flaps can be tailored to suit the needs of the defect and the area to be reconstructed, including variations in the following:
 - Design—eg, asymmetrical keystone in the calf
 - Mobilization—advancement, rotation, transposition, sliding
 - Grafting of the secondary defect
 - Single or double flaps—eg, yin-yang flap variant
 - Placement of V-Y points (best over convexities)
- Keystone flaps provide fasciocutaneous coverage of defects.
 - As a group, fasciocutaneous flaps are poorly suited to the reconstruction of complex three-dimensional defects where it is essential to obliterate dead space with filling with well-vascularized tissue.
- Keystone flaps are excellent at providing a simple and reliable approach to locoregional coverage and are sufficiently robust that they can be performed in conjunction with other flaps that will sit under the keystone flap (and can be tunneled under if necessary); thereby, providing vascularized soft tissue to fill a three-dimensional defect along with locally matching skin coverage.

TECHNIQUES

■ Keystone Flap Reconstruction of the Lower Leg

Markings

- Mark out the planned design that incorporates local pedicles and consider how the design will capture suitable venous drainage for the flap (**TECH FIG 1A,B**).
- Modify the design as required to maximize the potential for closure of both the defect and donor site (eg, the cone shape of the leg responds well to asymmetrical Keystone flaps (that are wider superiorly than inferiorly).
- Determine the nature of flap mobilization into the defect and plan in reverse around any pivot points.

Islandization of the Flap

- Apply a tourniquet to facilitate flap elevation where appropriate.
- Full islandization of the keystone flap promotes even tension across the flap (avoiding linear or point tension) and may augment cutaneous perfusion within the flap³ but must be weighed against the added scar burden.
- Where significant skin elasticity is present, it may be possible to minimize incisions on the donor defect side of the flap while still performing V-Y advancement of the rest of the keystone flap.
- The skin is sharply incised while preserving underlying neurovascular structures (particularly venous drainage) (**TECH FIG 2A**).
- Blunt dissection and targeted release of fascial or skin retaining ligaments and similar fibrous structures are undertaken as necessary while maintaining the integrity of the vasculature and lymphatics (**TECH FIG 2B**).
- Islandization of the fascia is undertaken if necessary, by sharp incision with scissors through small windows in the subcutaneous tissue (**TECH FIG 2C**).
 - Islandization is undertaken only to the degree to which is it required to achieve flap mobilization and closure.
- Dissection of perforators is rarely necessary but, when performed, care to should be taken to divide supporting connective tissue structures that might otherwise impede blood flow following mobilization of the flap.

TECH FIG 1 • A. A complex defect of the left leg involving an exposed plate for fixation of a compound tibial plateau fracture. Flap reconstruction is planned following debridement, washout, and confirmation of minimal bacterial contamination through wound swabs for microscopy, culture, and sensitivity. The anterior tibial artery was injured in the fracture, but the peroneal and posterior tibial vessels were intact. There was obvious undermining superiorly and inferiorly to the defect. Lateral tissues would be most appropriate as the basis for a keystone flap in this setting. **B.** An asymmetrical keystone perforator flap is designed to take advantage of cutaneous perforators from the peroneal and posterior tibial vessels. The flap makes good use of the lateral calf tissue but does not cross the axis of knee movement superiorly (on the right) and the diameter of the flap is larger than the defect width to ensure capture of perforators and ready availability of soft tissue to close the wound.

TECH FIG 2 • A. Islandization of the skin is performed by sharp incision while preserving the underlying soft tissues that contain important superficial venous drainage, lymphatics, and nerves. **B.** Blunt dissection is performed to retain important subcutaneous neurovascular structures (particularly superficial venous drainage seen on the right of the flap). The deep fascia is intact here with the exception of the existing defect. Flap closure of the defect was still not possible at this point; therefore, fascial islandization was performed. **C.** Fascial islandization is performed using partially open scissors and a pushing technique so as to minimize the risk of injuring nearby structures. This can be performed through small windows in the subcutaneous tissue so that neurovascular structures can be maintained. The leading edge of the flap is also mobilized (at the edge of the defect).

Assess Flap Viability and Achieve Definitive Hemostasis

- Following mobilization of the flap, the tourniquet is released so the viability of the keystone flap can be assessed.
 - The site and contribution of individual perforators can be assessed at tourniquet release as blood flows back into the flap.
- It is typical for keystone flaps to demonstrate hypervascularity initially and they may display a 3% to 5% increase in cutaneous perfusion secondary to changes in blood flow from the process of flap islandization.
- Initially, the flap may resemble venous congestion, but venous changes should not be present beyond 10 to 15 minutes following release of the tourniquet (as assessed by the presence of rapid capillary return).
- It is ideal to achieve hemostasis at this time and consider whether a drain should be placed.

Strategic Suturing

- Even physiological wound tension is one of the key elements to the success and good long-term aesthetic results seen with well-performed keystone

flaps.

- Skin is normally under tension, and keystone flaps are typically under some tension upon closure.
 - Single lines of tension or point tension should be avoided as these are not tolerated well by the skin, including keystone flaps.
- Islandization can be helpful to ensure even tension across the flap.
- Excess flap tissue (common at the obtuse angles of the flap beside the defect) can be trimmed safely to facilitate wound closure.
- The generation of even tension begins with the placement of strategic sutures across both the defect and the donor site to induce creep across both wounds and the flap (**TECH FIG 3A,B**).
 - Creep results in some relaxation of the tissues and promotes a more even tension at final closure.
 - Mattress sutures are ideal as these provide for the induction of creep alongside wound eversion to improve the resulting scar.
- A fine continuous suture helps ensure eversion and even tension.
- The “hemming suture” (two horizontal mattress sutures followed by a simple suture) may be used as a means of closure (**TECH FIG 3C,D**).

TECH FIG 3 • A. Following release of the tourniquet and hemostasis, strategic mattress sutures are placed, including tacking closure of the defect and the opposite side of the flap to induce creep and maximize even tension. The residual flap tissue at the leading edge of the flap has been trimmed. **B.** V-Y closure has been performed and further strategic mattress sutures have been placed to produce even physiological tension on the wound. **C.** A continuous skin suture (eg, Hemming mattress) is placed to ensure even tension and a nicely everted suture line for optimal aesthetic results. A suction drain is noted in the left of field, and this helped to minimize dead space in the otherwise planar defect. **D.** Anterior view of the flap at the point of V-Y closure to demonstrate even physiological tension and good contour following wound closure. Minor wound edge cones will resolve

on the convex surface of the leg in the following weeks to months without the need for revision.

■ Keystone Flap Reconstruction of the Axilla

- **TECH FIG 4** is the case of a patient with medically refractory hidradenitis suppurative of the left axilla who underwent excision of the involved axillary tissue and reconstruction with a lateral intercostal perforator-based keystone island flap (see **TECH FIG 4**).

TECH FIG 4 • A. Medically refractory hidradenitis suppurative in the left axilla prior to excision. **B.** The area to be excised is marked along with a lateral intercostal perforator-based keystone perforator island flap. The breast base is marked anteriorly with a dotted line to ensure that the reconstruction does not involve the breast directly. **C.** Following excision, partial closure is performed in the arm, analogous to a brachioplasty, leaving a defect that is 15 cm by 10 cm and not able to be closed directly while still maintaining shoulder movement. **D.** The skin of the flap is incised to form an island with elevation of the

tissues as necessary to facilitate transposition into the defect. **E.** Blunt dissection is performed to the undersurface of the flap to divide fascial attachments to the lateral chest wall, yet preserving all neurovascular structures where possible. **F.** Placement of strategic deep sutures begins with those for closure of the primary defect. **G.** Strategic suturing around the periphery ensures even tension before skin sutures are placed. Potential delays in wound healing are anticipated in the axilla, so interrupted sutures are used in this area. **H.** Full closure is completed with deep dermal and subcuticular sutures for the rest of the wound. Note that all of suture lines run around the perimeter of the breast, including into the lateral aspect of the inframammary fold and V-Y closures in the periphery, have maintained good contour and shoulder movement despite the size of the primary defect.

PEARLS AND PITFALLS

Poor donor sites

- The subcutaneous border of the tibia has no perforators and few direct vessels. Keystone flaps may be designed on either side of pretibial defects, but should not be designed directly over the tibia if possible. The scalp has direct vessels, but no perforators, and therefore, is not generally suitable for keystone flaps.

Flap mobilization

- Understanding the underlying muscle and fascial arrangements will facilitate ease of flap movement into the defect (eg, coverage of spinal defects using flaps on either side of the spine, but not above or below).

Aesthetics

- Consider modification of keystone flap margins to lie in natural skin creases or within aesthetic units as this improves their

	appearance and minimizes scar burden.
Dissection	■ Avoid overdissection of vascular structures. Only mobilize sufficiently to achieve wound and donor defect closure. Further dissection wastes time and puts important neurovascular structures at risk.
Skin grafting	■ Retain all skin trimmed from the keystone flap until the end of the case as this can be useful as donor skin for any skin grafting that might be necessary toward the end of the case.
Design experience	■ Plan a keystone flap for every defect but only use it if necessary and/or appropriate. This will rapidly increase experience with keystone flap planning.
Distal extremities	■ Use an oblique flap orientation to increase the available circumference for closure and have a low threshold for skin grafting of secondary defects.
Contour	■ Mobilization by transposition or elements of rotation produce a convexity, whereas advancement produces a more planar reconstruction. Consider matching the type of mobilization to suit the needs of the defect to enhance esthetics.
Documentation	■ An operative note that includes a diagram or photo of the flap planning and eventual closure is very useful. ■ In some circumstances, it may be difficult to identify the scars of keystone flaps, since scar generation is minimal in older individuals and the keystone design is not an obvious geometric pattern recognized by the human eye. ■ Where the defect was from oncologic surgery, positive margins may require a thorough understanding of the nature of flap mobilization so that further resection can be performed effectively if necessary.

POSTOPERATIVE CARE

- Following closure, if movements across joints adversely impact the integrity of the flap closure, then splinting is recommended.
- Splinting is rarely needed for more than 3 to 5 days.
- If the reconstruction is associated with an underlying musculoskeletal injury that requires immobilization, this takes precedence.
- Keystone flaps are very robust and are tolerant of being dependent for short periods in the immediate postoperative setting.
- Keystone flaps are suitable to ambulatory surgery.

- Encourage elevation of the limb to limit postoperative swelling, but it is rare to need to immobilize patients.
- If closure is tight, then splinting will limit the risk of wound dehiscence during the period of postoperative edema (3 to 5 days).
- Keystone flaps do not require specific monitoring in general.

OUTCOMES

- Keystone flap reconstruction is a straightforward approach to fasciocutaneous reconstruction that is well tolerated by patients and has a low complication profile relative to other forms of flap reconstruction.
- A retrospective analysis of 200 consecutive keystone flaps for head and neck reconstruction demonstrated a 2% flap revision rate for partial flap necrosis and a single complete flap loss.⁴ This compares very favorably to other forms of fasciocutaneous flap reconstruction in the head and neck.

COMPLICATIONS

- Keystone flaps are robust as evidenced by their relatively low partial and total flap loss rates.
- Minor complications can occur in up to 15% of cases in the head and neck with local wound issues including suture abscess, cellulitis, and wound dehiscence being the most common forms.⁴
- Donor site morbidity is very low, secondary to the conservative nature of flap dissection, including minimal dissection of muscle.

Section V: Amputation and Replantation

43 **Amputation of the Lower Extremity: Toes, Foot, Ankle**

CHAPTER

Kedar S. Lavingia and Jason T. Lee

INTRODUCTION

- Partial foot amputation (PFA) is a common sequel to advanced vascular disease secondary to diabetes and its complications.¹
- PFA may also occur due to injury, infection, cancer, or birth defect.
- PFA affects approximately 2 per 1000 patients in western countries, making it the most common type of amputation surgery.²
- PFA is associated with a significant failure rate and numerous complications including skin breakdown, ulceration, and equinus contracture, which can lead to subsequent and more proximal amputation.
- Thoughtful patient selection, early involvement of neuropsychiatry and physical medicine and rehabilitation (PM&R) are fundamental to a successful outcome.

BACKGROUND/CONSIDERATIONS

Forefoot Amputation

- Toe disarticulations are quite challenging when dealing with the remaining cartilage of the involved metatarsal head and possible complications of residual osteomyelitis.
- Ray amputation, which involves the excision of the toe and part of the metatarsal, provides a more viable option of ensuring an adequate surgical

debridement of the septic margins if that is the indication.

- Indications may include a wet or dry gangrene of a toe, osteomyelitis of the metatarsal head and/or proximal phalanx, septic arthritis of the metatarsophalangeal joint, and gross infection of the toe.
- Suggested inclusion criteria by a variety of authors for this type of amputation may include one or two palpable pedal pulses, ankle brachial index (ABI) ≥ 0.8 , and toe brachial index ≥ 0.7 .³
- In recent studies, absence of pulses, delayed capillary filling, high erythrocyte sedimentation rate, high creatinine, and high neutrophil counts were found to be predictive factors for a poor clinical outcome.⁴
- Indications for transmetatarsal amputation may include wet or dry gangrene involving only the forefoot and/or infection involving the forefoot, whereas the inclusion criteria are the same as those mentioned above required for a ray amputation.
- Amputation at the metatarsal level causes a muscular imbalance due to resultant equinovarus deformity from unopposed action of gastrocnemius, tibialis anterior, and tibialis posterior tendons, which is coupled with the deficiency of the muscular tension of the extensor tendons.^{5,6}

Midfoot Amputation

- Lisfranc disarticulation is a disarticulation through the tarsometatarsal joint, whereas Chopart disarticulation is a disarticulation through the talonavicular and calcaneocuboid joints leaving only the hindfoot (talus and calcaneum) behind (**FIG 1**).
- These amputations are rarely performed in diabetic foot infections due to high failure rate and the proximity of infected tissue to the heel pad.⁷

Hindfoot/Ankle Amputation

- This category included the amputations such as Syme amputation and has the indications and inclusion criteria as mentioned in the forefoot amputation category (**FIG 2**).
- Syme amputation has been advocated for trauma cases; however, Syme amputation can give good results in patients with diabetic foot infections.⁸
- Syme amputation should be reserved for patients with at least a palpable posterior tibial pulse and an ankle-brachial index of more than 0.5.

SURGICAL MANAGEMENT

Preoperative Planning

- All patients undergoing an amputation should be evaluated by both neuropsychiatry and PM&R early.
- Prevention and early detection of future disease should be discussed with the patient.
- Education on pressure-area pathogenesis is important as part of a strategy to encourage the patient to prevent further problems.
- Cardiac optimization is important given the high incidence of cardiac disease among this patient population.
- If discussing limb viability from trauma, a multidisciplinary approach involving vascular, orthopedics, and plastics should take place prior to proceeding with amputation.

FIG 1 • Midfoot amputation.

FIG 2 • Hindfoot/ankle amputation.

TECHNIQUES

Toe Amputation

- Place the patient supine with a small bump under the ipsilateral foot if desired.
- Incision lines are marked on the skin as appropriate for the planned amputation.
- For a partial toe amputation, a plantar-based flap is commonly used. However, several other possibilities exist (eg, dorsal flap, side-to-side flap, and fish-mouth flap).⁹
- The most important principles are to ensure that the flap is viable before closure and to perform a tension-free repair.
- All necrotic tissue is debrided. If infection is present, the tendon sheaths must be drained of any purulent material, which often tracks along them.
- Microbiology samples may be sent for culture and sensitivity testing.
- Neurovascular bundles are ligated or cauterized as they are dissected.
- If the wound is left open, many dressing options are available. Commonly, the wound is loosely packed with gauze soaked in saline or povidone-iodine. Generous amounts of cotton dressing and ACE bandages are then applied.

- If conducting an osteotomy, dissection is carried down to the periosteum, and a bone cutter or pneumatic saw is used to perform the osteotomy at the appropriate level.
- It is important to be mindful of tendon insertions and to consider the biomechanical effects that sacrificing these will have; disruption may predispose to further surgical intervention in the future.

Transmetatarsal Amputation

- A curved fish-mouth incision is made just proximal to the infected tissue of the foot (**TECH FIG 1**).
- The incision runs from the midshaft of the fifth metatarsal laterally to the midshaft of the first metatarsal medially through a midplane axis and carried circumferentially. The plantar flap is left longer to allow for closure. Also, the residual flap should be little longer on the medial side than on the lateral side again to aid with closure.⁹
- The incision is again circumferential and extended downward to bone. As the incision is deepened, hemostasis is achieved by means of cautery and/or vessel ligation with ties. The bony landmarks of the metatarsals are identified and presented by means of a periosteal elevator. The metatarsals are cut with a saw, and the bony ends are rounded with a bone file.¹⁰
- The wound is copiously irrigated and adequate hemostasis is achieved.
- Standard synthetic braided suture is used for closure of muscular and subcutaneous layers. Skin closure with synthetic nonbraided suture results in low skin tension and good approximation. Staples may also be added and dressing applied.

TECH FIG 1 • A–D. Transmetatarsal amputation.

■ Midfoot Amputation (Lisfranc/Chopart)

Lisfranc Amputation

- The proximal incision passes over the dorsum of the foot at the base of the metatarsals. The plantar incision is placed distally so that the infected material is removed, but the flap is long enough that it may be tailored later to cover the ends of the resected bones.
- The tarsometatarsal joints are disarticulated at the first, second, and third metatarsal bases. The fourth and fifth metatarsal bases are cut through with a motorized saw and left in the residual foot.
- On occasion, it may be necessary to leave the third metatarsal base in place to provide a better surface to support the local soft tissues.
- The residual foot is then dissected from the plantar surface, starting at the level of the short flexor muscles. The flap is then beveled to the distal edge.
- The wound is then checked for any residual infectious tissues and for hemostasis. It is tailored to close without tension.

Chopart Amputation

- Amputation of the forefoot at the talonavicular and calcaneocuboid joints closely resembles that of amputation at the tarsometatarsal joints.
- The plantar flap is long enough to fold up to the dorsum of the foot. In infected cases, no bone trimming is performed. In noninfected cases, the distal surfaces of the calcaneus are rounded to relieve potential pressure points.

■ Ankle Amputation (Syme Amputation)

- The anterior incision of the Syme amputation extends across the ankle just distal to the tip of each malleolus.
- The posterior incision extends from the malleoli vertically and also transversely across the heel.
- The extensor tendons are all divided at the level of the skin incision.
- The dorsalis pedis artery and vein are then identified, ligated, and divided.
- The ankle joint capsule is incised while plantar-flexing the foot. The medial and lateral ankle ligaments are divided.
- The tendons of the posterior tibialis and flexor hallucis longus are transected,

taking care to avoid injury to the posterior tibial artery. This will be the sole blood supply to the flap.¹¹

- The heel fat pad is carefully dissected by staying close to the calcaneus to avoid creating a buttonhole, which can doom the operation. The ankle joint is disarticulated and the foot is passed from the table.
- In a single-stage amputation, the malleoli are divided with a saw at the level of the articular surface of the tibia and the width is reduced by vertical bone excision. Holes are drilled in the medial, anterior, and lateral parts of the distal tibia and fibula to secure the heel pad directly under the tibia.¹²
- In a two-stage Syme amputation, the wound is closed by suturing the heel flap to the dorsal fascia. Six weeks later, the malleoli are removed through separate vertical incision.¹³

PEARLS AND PITFALLS

Indications	■ A careful and complete history and physical examination are essential. Preoperative studies are necessary to plan the resection and reconstruction. Vascular supply to planned reconstruction and amputation must be assessed prior to procedure.
Surgical incision	■ A long plantar flap leads to a better end-bearing stump. Leaving a flap to short will lead to complications and wound break down.
Infections/flap necrosis	■ Intravenous antibiotics and surgical debridement may be necessary to treat deep infections. Early diagnosis and treatment can affect outcome. Do not delay treatment if suspected infection after amputation.
Postoperative management	■ Keep the wound wrapped in sterile soft dressings and a pressure wrap for 3–5 days and physical therapy and rehab should be consulted early in the course.

POSTOPERATIVE CARE

- Keep the wound wrapped in sterile soft dressings and a pressure wrap for 3 to 5 days.
- Staples/sutures will remain in place for approximately 2 weeks.
- Physical therapy and PM&R should be consulted early.

Amputation of the Lower Extremity: Above-Knee Amputation, Below-Knee Amputation, Through-Knee Amputation

44 CHAPTER

Anahita Dua and Jason T. Lee

INTRODUCTION

- Approximately 1.7 million Americans are living with the loss of a limb, and this number is expected to nearly double by 2050.¹
- Amputations of the lower extremity may be performed for a myriad of reasons including infection, trauma, cancer, and pain.
- Thoughtful patient selection, early involvement of neuropsychiatry, and physical medicine and rehabilitation (PM&R) are fundamental to a successful outcome.

APPROACH CONSIDERATIONS

- Before considering an amputation, the patient should be evaluated by vascular surgery to ensure no other options (endovascular or open) exist.
- Patients who are suited for an above-knee amputation (AKA) include those who have limited or no mobility, a nonfunctional limb, infection that has progressed above the knee, inadequate overlying skin/muscle to provide stump coverage, and those patients who do not have adequate blood flow to heal a below-knee amputation (BKA) incision (popliteal pressures less than 50 mm Hg).
- BKA is suited in patients who wish to ambulate with a prosthesis, do not have extensive infection above the knee joint, and have popliteal pressures greater

than 50 mm Hg to heal the stump.

- Knee disarticulations (through-knee amputations) represent less than 2% of all amputations and are typically performed for trauma; they are best suited for patients who are unlikely to ambulate.
- AKA is also suitable for patients unlikely to ambulate, but cannot be performed in patients with inadequate femoral artery blood flow as the AKA stump will not heal.
- Severe infection that involves the femoral head or proximal femur also preclude AKA.²

PREOPERATIVE PLANNING

- All patients undergoing an amputation should be evaluated early by both neuropsychiatry and PM&R.
- Thorough physical exam and arterial pressures should be used to determine which level (AKA or BKA) is best for the patient (**FIG 1**).
- Cardiac optimization is important given the high incidence of cardiac disease among this patient population.
- If discussing limb viability status post trauma, a multidisciplinary approach involving vascular, orthopedic, and plastic surgery services should take place prior to proceeding with amputation.

FIG 1 • Incisions for above-knee (AKA), below-knee (BKA), and through-knee amputation.

TECHNIQUES

■ Above-Knee Amputation

- Place the patient supine with a small bump under the ipsilateral hip to internally rotate the leg.
- Outline the circumferential incision (fish mouth configuration)—amputation

level should be at the proximal femur, midfemur, or supracondylar.

- Sharply dissect the skin, soft tissue, and muscle down to the femur.
- Identify the vascular bundle and individually suture ligate the artery, vein, and nerve—nerve should be transected as proximally as possible.
- Using a periosteal elevator, elevate the femoral periosteum.
- Transect the bone using a Gigli saw or battery-operated oscillating saw.
- Bevel the femoral edge using the saw.
- Utilize a rasp to smooth the bone edge.
- Irrigate the wound thoroughly.
- Complete the amputation with the amputation knife.
- Approximate the anterior and posterior flaps with 0-Vicryl for deep fascia and 2-0 Vicryl for superficial tissue using interrupted figure of eights.
- Staple or suture the skin with 2-0 nylon.
- Cover skin wound with antibiotic ointment, petroleum jelly dressing, and cotton dressings for padding. Wrap a circumferential compressive elastic dressing for the stump.

■ Below-Knee Amputation

- Place the patient supine with a bump under the ipsilateral thigh and place a thigh tourniquet.
- Prep the lower extremity circumferentially up to the midthigh.
- The anterior incision is placed 10 cm distal to the tibial tubercle (anterior incision 2/3 total circumference), and the posterior incision (1/3 total circumference) should be long enough to ensure flap coverage (typically 1.5 times the length of the anterior flap).
- Carry down the anterior incision sharply to the tibia.
- Carefully tie off the anterior tibial vessels with 2-0 silk suture.
- Dissect through the lateral and superficial posterior compartments of the leg.
- Using a periosteal elevator, remove the periosteum and soft tissue to expose a clean segment of bone to be transected.
- Using a Gigli saw or battery-operated saw, transect the tibia—bevel distal tibia cut at 45 degrees.
- Transect the fibula 2 cm proximal to the tibia.
- Remove the muscle and soft tissue with an amputation knife.

- In the posterior compartment, identify and ligate the peroneal and posterior tibial vessels with 2-0 silk.
 - Tie all nerves with 2-0 silk and transect sharply as proximally as possible.
 - Utilize a rasp to smooth the edges of the tibia.
 - Deflate the tourniquet and coagulate or tie off any bleeding vessels.
 - Close pretibial fascia with 2-0 Vicryl figure of eights in an interrupted fashion.
 - Staple or suture the skin.
 - Cover skin wound with antibiotic ointment, petroleum jelly dressing, and cotton dressings for padding. Wrap a circumferential compressive elastic dressing for the stump.
-

■ **Through-Knee Amputation**

- Mark the leg at knee level with a posterior soft tissue flap of sufficient length to close the incision without tension.
- Proximal thigh tourniquet is placed, the patient is prepped and draped, planned incisions are remarked, and the tourniquet is inflated without exsanguination.
- Incisions are created with sharp dissection and carried down circumferentially to the level of the knee, through the joint, and along the drawn posterior flap.
- Distal leg is removed from the operative field.
- Distal end of femur is shaved down from distal to proximal using a sagittal saw anteriorly, posteriorly, medially, and laterally.
- Do not manipulate the insertion of the adductor magnus muscle.
- Preserve cruciate ligaments and posterior capsule.
- Posterior articulating surface is shaved to cancellous bone.
- Identify the patella and advance it to cover the distal surface of the femur.
- Sew the quadriceps tendon to the cruciate ligament and posterior joint capsule so that the posterior surface of the patella is in direct contact with the distal end of the femur.
- Sew the hamstring muscles to the quadriceps tendon and posterior capsule using 2.0-polydioxanone (PDS) so the distal femur is covered.
- Place a closed-suction drain, such as a Jackson Pratt (JP) drain over the

myodesis, and trim the posterior flap so it can be sewn to the anterior flap using 2.0-Prolene vertical mattress suture.³

PEARLS AND PITFALLS

Posterior flap creation

- Ensure that the flap length is adequate for coverage without being too tight as a tight flap can result in necrosis of the closure.

Stump edema

- Swelling of the stump post operatively can result in wound healing complications as it places tension on the suture line. Wrapping the stump in a sterile ACE bandage for at least the first three days post operatively will assist with keeping the edema to a minimum.

Knee immobilizer

- A knee immobilizer is a good adjunct to help keep the knee joint straight during recovery. A straight and flexible knee joint is imperative to being able to use a prosthesis for ambulation. A knee immobilizer has to be used with caution as it can cause pressure wounds to the knee area of the stump. It should be removed under supervision daily during physical therapy to prevent pressure wounds.

POSTOPERATIVE CARE

- Keep the wound wrapped in sterile soft dressings and a pressure wrap for 3 to 5 days.
- Staples/sutures will remain in place for a minimum of 4 weeks.
- Drains may be removed when 24-hour output is less than 30 mL.
- Ensure no contractures by placing a knee immobilizer in patients with a BKA.
- Physical therapy and PM&R should be consulted early.
- Nonweight bearing for 2 weeks.
- Fit for prosthesis and advance rehabilitation in 3 to 6 months.⁴

Section VI: Lymphedema

45 Lymphaticovenous CHAPTER Anastomosis

Ann-Charlott Docherty Skogh and Martin Halle

DEFINITION

- Lower extremity lymphedema can either be primary, occurring as a structural or anatomical birth defect, or secondary following surgery and/or radiotherapy, trauma, infection, and other causes.
- Chronic lymphedema is a progressive condition where tissue remodeling lead to fibrosis and fat deposition if not treated adequately.
- Lymphedema can be severely disabling and affect the patient's daily life with difficulties in range of motion, fitting into normal clothing, and can also cause psychological distress.

ANATOMY

- The lymphatic system is composed of collecting vessels and lymph nodes.
- The lymphatic system of the lower extremities includes a superficial and a deep system divided by the muscle fascia-aponeurosis. Perforating lymphatic vessels interconnect both systems.
- The superficial system includes the interfascial and epifascial subsystems, where the latter is the most superficial one, located between the skin and the saphenous fascia (**FIG 1**).

FIG 1 • A. The lymphatic vessels of the lower limb drain into the inguinal and pelvic system and proximally to cisterna chyli. **B.** The sub- and intradermal lymph capillaries drain into deeper lymphatic collectors located below the dermis.

PATHOGENESIS

- Lymphedema can be primary, occurring as a structural or anatomical birth defect in which genetics seem to play a major role. Secondary lymphedema may occur after surgery and/or radiotherapy, trauma, infection, and other causes. Lymphatic filariasis following infection of invading pathogens is globally the most common cause of secondary lymphedema.¹
- The transport capacity of lymphatic drainage may be reduced by damage that further affects the homeostasis of the interstitium, including both the cellular and extracellular compartments.

- Lymphostasis with fluid accumulation in the tissues leads to inflammation and subsequent tissue remodeling of skin and subcutaneous tissues with fibrosis and fat deposition.

NATURAL HISTORY

- Untreated lymphedema tends to deteriorate with time, leading to fibrosis and fat deposition that occur at later stages. Inflammatory changes make the patient susceptible to recurrent episodes of erysipelas and cellulitis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Initially, there is a phase with reduced transport capacity without clinical swelling.
- Stage 1 lymphedema includes pitting edema that subsides with limb elevation, whereas elevation is not effective in stage 2, when fibrosis of the tissues may already be seen.
- Stage 3 includes increasing volume of the extremity with congestive dermatitis, trophic skin, and fat deposition.²
- A pitting test shall be performed with pressure applied to the affected area (ideally over the tibial bone) for at least 60 seconds with the examiners fingers. The absence of pitting confirms tissue remodeling and fat deposition, where lymphaticovenular anastomoses may be less successful and suction-assisted lipectomy shall be considered.³

IMAGING

- Imaging methods for lymphedema include radionuclide lymphoscintigraphy, indocyanine green (ICG) lymphography, and magnetic resonance lymphangiography.
- Lymphoscintigraphy can indicate the location of lymph collectors, but does not provide information about specific areas of occlusion.²
- ICG lymphography, on the other hand, visualizes real-time superficial lymph flow without radiation exposure.⁴

Video p7-c045

- ICG lymphographic patterns are categorized from normal linear pattern (stage 0) to abnormal dermal backflow patterns; splash (stage I), stardust (stages II–IV), and diffuse stardust (stage V) patterns with lymphedema progression of the lower extremity⁵ (**FIG 2**).

DIFFERENTIAL DIAGNOSIS

- Venous insufficiency
- Deep vein thrombosis
- Thrombophlebitis
- Erysipelas
- Renal failure
- Cardiac failure
- Neurofibromatosis
- Lymphangioma
- Others

FIG 2 • **A.** Right leg lymphedema. **B,C.** ICG images illustrating different flow patterns. Linear pattern (**D**), stardust pattern (**E**), and diffuse pattern as described by Narushima M, Yamamoto T, Ogata F, et al.

NONOPERATIVE MANAGEMENT

- Decongestive physiotherapy and compression garments have been the most common nonsurgical treatment methods in reducing edema volumes, although they are not curative.

SURGICAL MANAGEMENT

- Surgical treatment of lymphedema includes debulking surgery, suction-assisted lipectomy, vascularized lymph node transfer, and lymphaticovenular, lymphaticovenous, and lymphatico-lymphatic anastomosis.⁶
- Suction-assisted lipectomy is usually performed for late lymphedema, when edematous tissues have remodeled to adipose tissue, without remaining signs of pitting edema. However, there is still a lack of consensus whether vascularized lymph node transfer or lymphaticovenous anastomosis is the primary choice in pitting lymphedema.
- Surgical treatment of lymphedema with lymphaticovenular anastomosis has recently gained popularity due to better imaging systems together with recent technical advances in supramicrosurgery, including high magnification

operative microscopes and supramicrosurgical instruments.^{7,8}

Preoperative Planning

- Positive pitting test is of paramount importance for the prognosis, because the absence of pitting may reveal a certain degree of irreversibility of the lymphedema.
- Lymphoscintigraphy facilitates confirmation of the diagnosis.
- ICG lymphography is commonly performed using a photodynamic eye (PDE) camera (Hamamatsu Photonics, K.K, Hamamatsu, Japan), ideally in an outpatient setting for patient selection and subsequently repeated perioperatively.
- Preoperative markings of linear flow as well as dermal backflow areas, based on ICG imaging, facilitate selection of anatomical sites for multiple LVAs.

Positioning

- The patient is usually positioned supine or in a unilateral “frog-leg” position for better access to medial structures, depending on results from preoperative ICG imaging.

Approach

- The procedure may be performed under local anesthesia, whereas general anesthesia is recommended if any movement during surgery is to be avoided.
- The use of two or three microscopes can facilitate the performance of multiple anastomoses.

TECHNIQUES

■ Lymphaticovenous Anastomosis

- A volume of 0.3 to 1.0 mL ICG (Pulsion Medical Systems SE, Feldkirchen, Germany, 5 mg/mL) is injected intradermally into the first web space of the affected leg to locate lymphatic vessels suitable for anastomosis (**TECH FIG 1A,B**). Similarly, the technique can be used for upper extremity lymphedema, performed with intradermal injection into the first and fourth web space.
- A linear flow pattern segment confirmed by ICG lymphangiography is

chosen (**TECH FIG 1C,D**).

- A 15- to 30-mm incision transverse to the selected lymph vessel is performed into the deep layer of dermis. The remaining thickness of the dermis is gently dissected under meticulous hemostasis, avoiding injury to the subdermal lymphatic vessels and venules (**TECH FIG 1E**).
- If lymphatic vessels are difficult to locate, a complementary injection of 0.3- to 1.0-mL patent blue (Patentblau, Guerbet, Germany V, 25 mg/mL) can be administered intradermally, a few centimeters distal to the skin incision.
- Suitable subdermal venules (around 0.5 mm in diameter) are explored adjacent to the chosen lymphatic vessel (**TECH FIG 1F**).
- Preparation and alignment of vessels (**TECH FIG 1G,H**).
- A stent using 6-0 nylon suture that is placed into the lumen of the vessels may be used to facilitate anastomosis of the vessels, which range from 0.3 to 0.8 mm (**TECH FIG 1I,J**).
- Patent blue or ICG lymphography can be used to confirm patency of LVA (**TECH FIG 1K**).
- The venules of choice may differ in diameter compared to the lymphatic vessels, where different types of anastomoses may be applied. The first choice is an end-to-end anastomosis. If a Y-shaped venule is available, both afferent and efferent lymphatic flow can be diverted into the same venule⁹ (**TECH FIG 1L-P**).

TECH FIG 1 • **A.** Injection of indocyanine green into the first web space of the foot. **B.** ICG staining of lymphatic vessels in the foot as seen with PDE camera. **C.** Markings on the skin of the leg after injection of ICG. **D.** ICG staining of linear lymphatic vessels in the leg as seen with PDE camera. **E.**

PEARLS AND PITFALLS

- Choose small venules to avoid venous backflow.
- Tension-free anastomosis is of great importance due to the low-flow nature of lymphatic vessels and venules.
- Perioperative antibiotics are indicated due to long surgery time and an increased risk for erysipelas in lymphedema patients.
- The dorsum of the foot and lower leg are usually good locations to perform LVAs in the lower extremity. The lymphatic vessels are usually easy to find after examination with ICG, complemented with patent blue if necessary. The upper extremity presents a similar pattern, where it is easier to find suitable vessels on the dorsum of the hand and in the forearm compared to the upper arm.
- LVAs may be more difficult to perform in the thigh area due to the greater width of the epifascial compartment.

POSTOPERATIVE CARE

- Low molecular weight heparin is indicated the first postoperative week due to immobilization during surgery.
- Postoperatively, the leg is kept slightly elevated at night and a low-pressure bandage is applied the day after surgery to avoid interstitial swelling.
- Postop day 1, the patient is allowed to ambulate with full weight bearing with a low-pressure bandage applied (about 30 mm Hg), but with reduced physical activity.
- Normal physical activity can be resumed after 3 weeks.

OUTCOMES

- Several case reports of successful treatment of lower extremity lymphedema with LVAs are available, and multiple LVAs seem to be favorable.¹⁰
- Reduced number of episodes of erysipelas after LVAs has been reported.¹¹
- The outcome of lower extremity LVAs has been less investigated as compared to upper extremity LVAs, and data from prospective, controlled studies are scarce.

COMPLICATIONS

- Infections may occur in the postoperative period and shall be treated with antibiotics.
- Temporary local redness can occur due to venous backflow into the anastomosis.
- Deterioration of the lymphedema is a very rare complication, but can occur, after LVA surgery.

46 Lymphedema: Lymph Node Transfer

CHAPTER

Adrian S. H. Ooi and David W. Chang

DEFINITION

- The lymphatic system is responsible for reabsorption of excess interstitial fluid, protein, and waste products, as well as filtration and removal of foreign material from interstitial fluid and absorption of lipids from intestines. Up to 50% of the body's circulating albumin is processed through the lymphatic system every day.
- Lymphedema is an abnormal accumulation of protein-rich fluid in the interstitial compartment resulting in edema formation.
- It occurs when the generalized or regional lymphatic load exceeds its transport capacity.
- Long-standing lymphedema leads to chronic inflammation, adipose tissue hypertrophy and fibrosis, and eventually lymphatic channel fibrosis.
- Lymphedema is a problem that affects about 200 million people worldwide.
- Distribution: Lower limb 90% greater than upper limb 10% greater than genitalia 1%.

ANATOMY

- Endothelial cells bud off from veins during early embryonic development and transdifferentiate to form the lymphatic vasculature.
- The lymphatic primary plexus is composed of capillary-like vessels and is further remodeled to form pre-collecting, collecting, and ductal components. The major lymphatic ducts are formed by two paired lymph sacs (jugular and iliac) and two unpaired sacs (retroperitoneal and cisterna chyli).
- Lymphatic channels are thin-walled vessels composed of endothelial cells connected by discontinuous junctions and surrounded by smooth muscle. The

basement membranes of the larger, deeper lymphatic vessels have multiple intercellular gaps, which form valves through which fluid flows unidirectionally.

- The superficial dermal lymphatics are unvalved and drain into the valved subfascial deep dermal system, which run with the superficial veins.
- Lymphatic fluid is then transported through afferent lymphatic channels to lymph nodes, which are gathered in basins throughout the body. After undergoing immunological processes within the lymph nodes, the fluid flows out through efferent lymphatic channels and ultimately into the thoracic ducts and subclavian veins where they rejoin the venous circulation.
- Lymph nodes are bean-shaped structures distributed along the lymphatic channels. They consist of a capsule, an outer cortex and an inner medulla. Multiple afferent lymphatics can enter via the outer cortex, and a lymph node is supplied by an artery and a vein at the hilar region, which accompany a single efferent lymphatic vessel. The lymph nodes contain lymphocytes and macrophages, which are responsible for removal of organisms, foreign substances, and tumor cells.
- Lymph nodes are distributed deep in the body along the respiratory and gastrointestinal tract and superficial in the cervical, thoracic, and inguinal regions.
- Lymphatic fluid transportation is under humoral influences and is propelled by a combination of:
 - Smooth muscle surrounding the collecting vessels that have an intrinsic autocontractile mechanism
 - Extrinsic compression by neighboring skeletal muscles
 - Negative intrathoracic pressure

PATHOGENESIS

- Lymphatic homeostasis is a function of filtration of plasma across the capillary walls into the interstitial compartment and absorption by the lymphatic system. This rate of filtration is governed by the Starling equation whereby net filtration is determined by intra- and extracapillary hydrostatic and oncotic forces.
- Lymphedema arises when the rate of filtration exceeds absorption by 2 to 4 L/d.
- This disruption can occur at the level of the lymphatic vasculature or the lymph nodes and can arise due to a primary or secondary disease process.

- True primary lymphedema can be classified as congenital (Milroy disease), pubertal/praecox (Meige disease), and tarda, which occurs in the adult age group. Lymphedema praecox is the most common form of primary lymphedema.
- Lymphedema can also arise secondary to acquired damage to the lymphatic system. These include infection, trauma, malignancy, surgery, and radiation.
- The most common cause worldwide is filariasis, caused by the parasite *Wuchereria bancrofti*. In the developed world, it is most commonly due to treatment for cancer.
 - For breast cancer treatment, it occurs in up to 40% of cases with lymph node dissection and radiation and 5% of cases with sentinel lymph node biopsy.
 - 41% after gynecological cancer treatment.
 - 12% to 55% after groin lymph node dissection.

NATURAL HISTORY

- When there is disruption in the lymphatic system and as lymphatic pressure builds, flow within the lymph vessels stagnates, leading to valvular incompetence and dermal backflow.
- Lymphedema is confined to the subcutaneous compartment as the deeper lymphatics are driven by the skeletal muscle pump.
- Over time, macromolecular protein and hyaluronan are deposited in the interstitium leading to increased tissue colloid osmotic pressure.
 - Fibroblast, monocytes, adipocytes, and keratinocytes also increase within the tissue, leading to increased collagen deposition, degeneration of elastic fibers, and fibrovascular proliferation.
 - The basement membranes of lymphatic vessels are obliterated and the vessels become fibrotic.
 - This combination results in nonpitting edema, and eventually a chronic inflammatory state ensues.
- The cytokines arising from the inflammation and the disruption in lymphatic flow of lipids leads to adipose deposition and hypertrophy in the interstitium.
- The verrucous appearance of long-standing lymphatic extremities is caused by hyperplasia of skin at the dermal-epidermal junction.
- Lymphatic stasis and decreased immunological function predispose the patient to an increased risk of local skin infections, erysipelas, and later, lymphangitis. The excess tissue can lead to symptoms of pain, heaviness, and decreased mobility. Long-standing chronic lymphedema can lead to development of

lymphangiosarcoma (Stewart-Treves syndrome). Lymphedema has significant adverse impact on patients' quality of life and psychosocial health.

- The International Society of Lymphangology (ISL) has classified lymphedema into three stages:
 - 0: Latent/subclinical period
 - I: Pitting edema which is reversible on elevation
 - II: Tissue fibrosis and edema, which is nonreversible on elevation
 - III: Elephantiasis and trophic skin changes

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history is targeted at determining the diagnosis and etiology of lymphedema, duration, symptoms, and complications, and how the patient has been managing it.
 - Elucidating diagnosis and etiology include asking about risk factors for malignancy, travel history, prior surgical procedures, history of radiation therapy, trauma and infection, and family history. Obesity can contribute to lymphedema through the overload of lipids in the body. Other causes of extremity swelling such as congestive cardiac failure, venous insufficiency, and deep vein thrombosis have to be excluded (see differential diagnosis).
 - Important symptoms and complications to ask about include pain and infections in the affected extremity, a feeling of heaviness and difficulty in movement.
- The examination of the patient with lymphedema should include a general physical and a targeted examination of the affected part. The general examination is aimed at excluding any active infection or malignancy and general causes of extremity edema.
- Lymphedema is typically unilateral, with the swelling beginning distally and progressing over months to years.
 - The edema starts off soft and pitting and eventually becomes nonpitting as interstitial fibrosis sets in.
 - There is minimal pigment change or ulceration and peau d'orange indicating dermal fibrosis can be present.
 - Late changes in the extremity include hyperkeratosis, papillomatosis, and the development of a positive Stemmer sign in which the skin on the dorsum of the second web space of the foot cannot be pinched as a fold.
- Reproducible measurements of the limb should be taken to help with accurate follow-up. These can include circumference measurements and volumetric

measurements such as water displacement tests, perometry, and bioimpedance testing. Digital photographs are also useful for comparative analysis.

- Circumference measurements are typically taken at 4- to 10-cm intervals from consistent landmarks such as the patella in the lower extremity and the olecranon in the upper extremity. Figures that are used in the diagnosis of lymphedema include the following:
 - Greater than 2 cm difference from the nonaffected limb.
 - Severity can be graded as mild (greater than 10% difference), moderate (greater than 20%), and severe (greater than 30%).
- Water displacement has been the standard for volume measurement and is highly accurate but cumbersome. Lymphedema is diagnosed if the volume differential of the affected limb is greater than 10% of the normal limb.
- Perometry utilizes an infrared optical electronic scanner to calculate volume.
- Bioimpedance testing calculates the fluid composition of an affected limb using resistance to an electrical current.

IMAGING

- Lymphangiography is the visualization of lymphatic vessels using contrast medium. Vessels can be classified as anaplastic, hypoplastic, or hyperplastic. There are the direct and indirect forms of lymphangiography.
- Direct lymphangiography involves transecting distal lymphatic vessels and directly injecting water-soluble iodide contrast medium into them. This has largely been abandoned because of patient discomfort and damage to the lymphatic channels.
- Indirect lymphangiography injects contrast medium distally into the subepidermis and uses radiographic imaging to delineate the lymphatic system.
- Isotopic lymphoscintigraphy is the current standard for lymphatic imaging. It injects Technetium-99–labeled albumin into the subepidermis of the distal affected extremity and timed post injection imaging to determine lymphatic anatomy and function. It has a sensitivity of 97% and specificity of 100%. However, when done awake, the injection can be painful, and the length of time required can be distressing to the patient.
- The injection of indocyanine green (ICG) and imaging using an infrared camera have become widely used in the imaging of lymphatic vessels and are particularly useful intra-op when needing to delineate the superficial lymphatic system. A classification based on the appearance of the ICG has been

developed and correlated with the Campisi classification (Table 1).¹

- Computed tomography (CT) and magnetic resonance imaging (MRI) scanning are useful in determining the architecture of the affected limb and elucidating any underlying cause such as neoplasm. There is commonly a “honeycomb” appearance above the deep subcutaneous fascia. MRI with contrast has proven promising in outlining lymphatic vasculature.²

Table 1 Indocyanine Green Appearance to Classify Severity of Lymphedema

Stage	Description
0	No dermal backflow
I	Splash pattern around the axilla/groin region
II	Stardust pattern proximal to the patella/elbow
III	Stardust pattern distal to the patella/elbow
IV	Stardust pattern in the entire limb
V	Diffuse pattern

DIFFERENTIAL DIAGNOSIS

- Venous insufficiency
- Deep venous thrombosis
- Vascular malformations
- Lipedema
- Myxedema
- Fluid overload
 - Congestive cardiac failure
 - Renal failure
 - Liver failure
- Hypoalbuminemia
- Soft tissue tumors
- Morbid Obesity

NONOPERATIVE MANAGEMENT

- Nonoperative management is aimed at reducing the amount of swelling and treating any resulting complications. The former is accomplished by

compression and massage therapy, whereas the latter involves adequate skin care and early detection of infection and treatment with the appropriate antibiotics. In a compliant patient, this helps to slow down the progress of lymphedema.

- Patients should be educated about lymphedema and its complications, and given responsibility for their own care.
- Conservative treatment of lymphedema has been well researched and the regimen described is complete decongestive therapy (CDT). This should be started early to have the most benefit and is useful in cases of lesser than stage III lymphedema. Analyses have shown up to 40% to 60% reduction in lymphedema volume. It consists of two phases:
 - Initial reductive phase (up to 8 weeks) consisting of:
 - Manual lymphatic drainage—Circular tissue stretching massage with varying degrees of pressure
 - Compression therapy during waking hours
 - Regular skin care
 - Targeted exercise
 - Maintenance phase consisting of
 - Self-conducted lymphatic drainage
 - Continuation of compression garments
- Weight loss may help with lymphedema by reducing the flow of fatty acids through lymphatic channels and decreasing fatty deposition in the subcutaneous tissue.
- Exercises such as swimming can be useful in reducing the severity of lymphedema.
- Unsubstantiated nonoperative measures include coumarin (5,6 benzo-a-pyrone), diuretic use, microwave heating, and intra-arterial injection of lymphocytes.

SURGICAL MANAGEMENT

- Although significant advances have been made in the surgical treatment of lymphedema, no surgical technique offers a cure, and an aggressive trial of nonsurgical therapy should first be done.
- Indications for surgical treatment include failed conservative therapy, grossly impaired limb function, debilitating extremity size and weight, recurrent lymphangitis (greater than 3 episodes of infection per year), and uncontrolled

pain.

- Surgical techniques for the treatment of lymphedema are classified as excisional and physiological.
- Excisional techniques aim to reduce the amount of lymphatic tissue and tighten the skin envelope. They are described elsewhere in this book and include but are not limited to excision and skin grafting (eg, Charles procedure), staged excision, liposuction, and, more recently, radical resection with preservation of perforators (RRPP).³ Unfortunately, as the primary disease process is not addressed, there is a high risk of recurrence with these techniques, and the appearance can be undesirable.
- Physiological techniques attempt to replicate the normal lymphatic flow in the affected extremity. Procedures that have been developed and described elsewhere include buried dermal flaps, lymphovenolymphatic bypass, lymphatic bypass, and lymphovenous anastomosis (LVA).⁴
- The vascularized lymph node transfer (VLNT) is a physiological technique that transfers intact autologous lymph nodes from a nonlymphedematous region of the body to the affected extremity. In a sense, this is the most physiological method of addressing the problem in a patient whose lymphedema is due to damage to or paucity of lymph nodes in a particular basin.
- The lymph nodes are microsurgically anastomosed to the chosen recipient site vessels and allowed to develop collateral blood supply. Over time, reported mechanisms of lymphedema reduction include reduction of scarring at the recipient site, hydrostatic “pumping” of intraflap lymph via arterial inflow and venous outflow, and lymphangiogenesis aided by the production of VEGF-C by the transplanted lymph nodes.
- Though not curative, physiological techniques have proven to alleviate symptoms and reduce lymphedema volume.

Preoperative Planning

- Preoperative workup should include elucidating etiology of the lymphedema, comorbidities, the patient’s treatment to date, limb measurements, weight fluctuations, and ability to comply with therapy.
- Severity of lymphedema should be clinically staged according to the ISL grading system, and treatment planned accordingly:
 - Patients with mild to moderate stage 1 or 2 lymphedema are best candidates

for physiologic procedures such as VLNT and/or LVA.

- Patients with stage 3 fibrofatty lymphedema or elephantiasis may benefit from excisional procedures prior to physiologic procedures in order to offset the lymphatic load and optimize the result of physiologic procedures.
- Specific history to note with regard to vascularized lymph node (VLN) harvest includes previous surgery in the region of planned harvest or pre-existing lymphedema if harvest is planned from the groin. Scars and surface anatomical landmarks should be noted. Active infection in the affected extremity should be ruled out.
- Definitive diagnosis of lymphedema is made with lymphoscintigraphy, which evaluates lymphatic function.
- ICG imaging of the affected extremity prior to surgery aids in lymphatic mapping for the simultaneous performance of LVA.
- If groin VLNT is planned, reverse lymphatic mapping should be performed to determine the crucial deep groin lymph node basin of the lower extremity, which should be avoided in groin VLNT harvest.
 - This involves the preoperative injection of technitium-99–labeled albumin subcutaneously into the inner thigh and a gamma probe used intraoperatively to detect the sentinel lymph node of the deep groin lymph node basin.⁵
 - Harvest of this lymph node should be avoided at all costs to prevent postoperative lower extremity lymphedema.

Positioning

- For most VLN harvest, the patient is placed in a supine position.
- For TAP flap or split LD flap with LNT, the patient is placed in lateral decubitus position.
- If the lymph nodes are intended to be placed in the axilla, the arm is extended at right angles to the torso to access and prepare the recipient site.
- For specific points for each source of VLN, refer to the subheadings below.

Table 2 Comparison of Different Vascularized Lymph Node Transfer Donor Sites

Donor site	Average Number of Lymph Nodes	Advantages	Disadvantages

Supraclavicular	2–3	• Inconspicuous donor site • Low risk of causing donor site lymphedema	• Variable anatomy • Need for meticulous harvest technique
Submental	3–4	• Consistent anatomy • Low risk of causing donor site lymphedema	• Visible donor site scar • Risk of injury to the marginal mandibular nerve
Thoracic	Variable	• Ability to harvest with latissimus dorsi or thoracodorsal artery perforator flap • Inconspicuous donor site scar	• Risk of upper extremity lymphedema
Inguinal	5–8	• Ability to harvest with abdominally based flap • Inconspicuous donor site	• Risk of lower extremity lymphedema
Omentum	Unknown	• No risk of causing donor site lymphedema • If harvested laparoscopically, minimal donor site scar	• Need to enter abdominal cavity • No skin paddle possible

Approach

- For harvest of VLN, the common sources are the submental, supraclavicular, thoracic, inguinal, and omental lymph nodes. The advantages, disadvantages, and potential complications of each are listed in Table 2.
- For recipient sites in the limbs, placement location and the need for a skin paddle for the VLNT are debated.
- Some surgeons prefer proximal placement of the lymph nodes, whereas others prefer distal placement. This is dependent on which mechanism the lymph nodes are thought to work.
 - For the “pumping” mechanism, distal sites such as the ankle and wrist are

chosen as gravitational forces aid in the flow of lymphatics.

- For the argument that VLNT works by promoting lymphangiogenesis, more proximal sites near the vicinity of lymph node damage are chosen. It is thought that dual effect of scar release and placement of well-vascularized lymph nodes enhance the restoration of lymphatic flow.
- It is likely that both mechanisms contribute simultaneously to the resolution of lymphedema. A conservative approach to recipient site selection is therefore the best approach.⁶
- The proximal site is chosen when there is a definite area of scarring from previous surgery or radiation.
 - When it is difficult to access or remove scars, the VLNT can be done distal to the site of obstruction. An example is in patients whose pelvic lymph nodes were removed via intra-abdominal surgery.
 - In patients who have no definite site of injury, placement of the VLNs directly proximal to the area of the swelling is effective.
- VLNT should be monitored if possible in most cases as in any other free tissue transfers. A skin paddle can be helpful when closure of native skin over the lymph nodes is tight, such as at the wrist, but is not cosmetically appealing. This can be resolved by excision of the skin paddle at a second stage.
- Our preference is to harvest supraclavicular lymph nodes without a skin paddle, and place them at the axilla for the upper extremity and the groin for the lower extremity.
- We use an implantable Doppler probe postoperatively to monitor the microanastomotic patency.

TECHNIQUES

■ Supraclavicular Vascularized Lymph Node Harvest

- Based on the transverse cervical (TC) artery.
 - The flap can be harvested with or without a skin paddle.
- Surface landmarks (**TECH FIG 1A**) are a triangle formed by the clavicle (inferior border), lateral edge of the sternocleidomastoid muscle (SCM;

medial border), and external jugular vein (lateral border).

- Lymph node harvest from the right neck is preferable to avoid the risk of damaging the thoracic duct in the left side of the neck. Lymph nodes are harvested from the left neck if the lymphedema involves right arm.
- In the supine position, the patient's head is tilted 45 degrees away from the side of harvest.
- A longitudinal skin incision is made 1 to 2 cm above the superior border of the clavicle between the medial and lateral borders (**TECH FIG 1B**).
 - If harvesting a skin paddle, the perforator to the skin should be marked with a Doppler probe prior to harvest and an ellipse marked encompassing the perforator along the line of the recommended skin incision.
- The platysma is breached with sharp dissection, and the omohyoid muscle or tendon is identified and cut to reveal fat and lymphatic tissue posteriorly (**TECH FIG 1C**).
- Medial dissection proceeds along the lateral border of the SCM. The internal jugular vein (IJV) is next identified, and the tissue within the triangle gently dissected off. The anterior scalene muscles are identified at the base.
- Proceeding inferiorly from the medial border, the TC artery can usually be identified arising from the thyrocervical trunk (**TECH FIG 1D**).
 - Pedicle length should be maximized by dissecting down to the source vessel.
 - There is usually an accompanying vein supplying the flap arising from the IJV or subclavian vein.
- The distal ends of the TC vessels are identified and ligated.
- Using the EJV as the lateral landmark, lateral dissection then proceeds in a natural plane medial to the trapezius muscle and stops once the anterior scalene muscles are identified at the base.
- Once the borders have been dissected, the supraclavicular VLN flap can be lifted off the anterior scalene muscles and the flap isolated on its vascular pedicle (**TECH FIG 1E**).
 - The phrenic nerve should be identified and preserved.
- When the recipient site is ready, the pedicle can be ligated.
- Donor site closure is done over a suction drain placed away from the IJV. The platysma is approximated with interrupted absorbable polyfilament sutures, and the skin is closed with a running subcuticular suture.

TECH FIG 1 • **A.** Surface marking of supraclavicular lymph node transfer. **B.** A longitudinal skin incision is made 1 to 2 cm above the superior border of the clavicle between the medial and lateral borders. **C.** The platysma is split with sharp dissection, and the omohyoid muscle or tendon is identified and cut to reveal fat and lymphatic tissue posteriorly. **D.** Proceeding inferiorly from the medial border, the thoracodorsal (TD) artery can usually be identified arising from the thyrocervical trunk. **E.** Once the borders have been dissected the supraclavicular VLN flap can be lifted off the anterior scalene muscles and the flap isolated on its vascular pedicle. (From Ooi AS, Chang DW. 5-step harvest of supraclavicular lymph

nodes as vascularized free tissue transfer for treatment of lymphedema. J Surg Oncol. 2017;115:63-67.)

■ Submental Vascularized Lymph Node Harvest

- Based on the facial artery and its submental branch.
 - The flap can be harvested with or without a skin paddle.
 - Surface landmarks are the symphysis, body and angle of the mandible, and facial artery.
 - The facial artery is palpated and marked as it crosses the inferior border of the mandible. The skin incision is made 1 cm posterior to the lower border of the mandible.
 - If a skin paddle is desired, a handheld Doppler probe is used to detect the perforators from the submental artery (SMA). An ellipse encompassing the perforators is designed extending from the symphysis medially to the angle of the mandible laterally, with the upper margin along the lower border of the mandible from the mandible angle to the symphysis. The initial skin incision is then initiated at the upper margin of the ellipse.⁷
 - The incision is deepened through the platysma, and the SMA is identified at its junction with the FA. The marginal mandibular branch of the facial nerve is identified as it crosses the FA and must be preserved. The SMA is dissected proximal to distal end along its axis.
 - The submental lymph nodes are found at the junction of the SMA and FA, and the soft tissue at this region is included to preserve the maximal amount of lymphatic tissue.
 - If a skin paddle is included, the septocutaneous perforator from the SMA to the skin paddle must be preserved. To aid with this, the anterior belly of the digastric muscle can be included with the perforator.
 - The distal ends of the facial vessels are ligated, and the submental lymph nodes are harvested with the submental vessels and the proximal facial vessels to maximize pedicle length.
 - The donor site is closed primarily over a suction drain. The platysma is approximated with interrupted absorbable polyfilament sutures, and the skin is closed with a running subcuticular suture.
-

■ Thoracic Vascularized Lymph Node Harvest

- Based on the thoracodorsal (TD) vessels or the lateral thoracic (LT) vessels:
 - The thoracic lymph nodes can be harvested as part of a muscle-sparing latissimus dorsi (LD) or thoracodorsal artery perforator (TAP) flap, which can be used for simultaneous pedicled breast reconstruction.
- A longitudinal line just anterior to the LD muscle and lateral to the breast is marked and incised (**TECH FIG 2A**).
- The TD pedicle is located as it enters the LD muscle, and the LT vessels can be identified just anterior to this as it hugs the serratus anterior muscle fascia.
- The lymph nodes to be harvested are located inferior to the lateral border of the pectoralis minor muscle (**TECH FIG 2B**). These are the level 1 lymph nodes of the axillary region, and harvest of these will avoid damage to the draining lymphatics of the arm.
 - If the lymph nodes alone are harvested, the LT pedicle is preferred as they are the preferential supply.⁸
 - If a pedicled LD or TAP flap is desired for breast reconstruction, the lymph nodes are captured as an anterior extension of the flap skin paddle. As the flap is transposed into the breast anteriorly the lymph nodes are swung upward and placed in the axilla (**TECH FIG 2C**).
- The donor site is closed primarily over a suction drain. The superficial fascia is approximated with strong absorbable polyfilament sutures, and the skin is closed with a running subcuticular suture.

TECH FIG 2 • **A.** A longitudinal line just anterior to the LD muscle and lateral to the breast is marked and incised. **B.** The lymph nodes to be harvested are located inferior to the lateral border of the pectoralis minor muscle. **C.** As the flap is transposed into the

breast anteriorly the lymph nodes are swung upward and placed in the axilla. (From Ooi AS, Chang DW. 5-step harvest of supraclavicular lymph nodes as vascularized free tissue transfer for treatment of lymphedema. J Surg Oncol. 2017;115:63-67.)

■ Inguinal Vascularized Lymph Node Harvest

- Based on the superficial circumflex iliac artery (SCIA) or occasionally on the superficial inferior epigastric artery (SIEA).
 - The lymph nodes can be harvested alone or as part of an abdominal flap for simultaneous breast reconstruction and VLNT.
 - For lymph nodes alone, the flap can be harvested with or without a skin paddle.
- Surface landmarks (**TECH FIG 3A**) are the anterior superior iliac spine (ASIS), pubic symphysis, inguinal ligament, and the femoral canal.
- Reverse lymphatic mapping is done for the side that lymph nodes are to be harvested from. This first involves the preoperative injection of technetium-99–labeled albumin into the medial thigh.
- The skin incision is made 2 cm superior to the inguinal ligament and deepened to the level of the cribriform fascia.
 - If a skin paddle is desired, a handheld Doppler probe can be used to detect the perforators from the SCIA, along a line 1 to 2 cm inferior to the inguinal ligament.
- The SCIA and SIEA are identified. The lymph nodes are located in the fat lateral to the SIE vessels and around the SCI vessels, superior to the inguinal ligament (**TECH FIG 3B**). Their superficial border is the Scarpa fascia and the deep boundary is the muscular aponeurosis.
- A gamma probe is used to locate the sentinel lymph node in the leg via reverse lymphatic mapping.
 - It is imperative that the sentinel lymph nodes along with the deeper lymph nodes that drain the leg are not included in the flap.
- Once the deep lymph nodes have been identified and kept away from the dissection, lymph node harvest can be completed.
- If an abdominal flap for breast reconstruction is planned together with the

VLNT, the lymph nodes should be harvested in continuity with the abdominal tissue along the SIE and/or SCI vessels. The pedicle of the abdominal flap (be it a perforator or muscle-sparing flap) is then anastomosed to the internal mammary vessels, with supercharging of the lymph node vein to an axillary recipient vein (**TECH FIG 3C**).⁹

- The donor site is closed over a suction drain, ensuring that Scarpa fascia is approximated before a running subcuticular suture for the skin. If an abdominal flap is taken, this is closed in the usual fashion.

TECH FIG 3 • A. Surface landmarking of inguinal lymph node transfer. **B.** The lymph nodes are located in the fat lateral to the SIE vessels and around the SCI vessels, superior to the inguinal ligament. **C.** The pedicle of the abdominal flap is then anastomosed to the internal mammary vessels, with supercharging of the lymph node vein to an axillary recipient vein. (**B,C:** From Ooi AS, Chang DW. 5-step harvest of supraclavicular lymph nodes as vascularized free tissue transfer for treatment of lymphedema. *J Surg Oncol.* 2017;115:63-67.)

■ Omental Vascularized Lymph Node Harvest

- The omentum has been called the guardian of the abdomen due to its lymphatic and immunological capability.
- The omental flap is based on the right gastroepiploic artery and can be harvested via an open or laparoscopic approach. A skin paddle is not possible.
 - For the open approach, an upper minilaparotomy incision is used.
 - For the laparoscopic approach, the abdomen is accessed with four ports.
- The lymphatic territory of the omentum can be identified with methylene blue dye injection preoperatively. This can be done using upper gastrointestinal endoscopy or via direct injection using the open or laparoscopic approach.
- The free border of the omentum is first identified. This is then dissected along its natural anatomical plane toward the greater curve of the stomach. Gentle manipulation of the omentum is required throughout the harvest.
- The lesser sac is entered and the short gastric and left gastroepiploic vessels are identified and ligated, and the flap is dissected off the greater curve of the stomach with meticulous cautery.
- The flap is harvested in its entirety based on the right gastroepiploic artery, which is dissected to its origin. It can be debulked by up to 40% to aid in inset.
 - Preoperative dye mapping aids in preserving the critical lymphatic tissue.¹⁰
- Once the flap is rendered ischemic, delivery of the flap extra-abdominally can be done via the minilaparotomy incision or, in the case of the laparoscopic approach, a 3-cm infraumbilical extension of the umbilical port.
- The laparotomy or laparoscopic wounds are closed in the usual fashion.

■ Recipient Site Preparation and Microanastomosis

- As mentioned previously, recipient site is dependent on clinical indication and surgeon preference. The advantages and disadvantages of each are summarized in Table 3.
- In the upper extremity, the lymph nodes are commonly placed in the axilla or at the dorsal wrist.
- In the lower extremity, the lymph nodes are commonly placed in the groin,

anterior ankle and less commonly, the popliteal region.

Axilla

- A skin paddle is usually not required for VLNT to this region.
- If available, a previous axillary scar is used for the skin incision.
- The incision is deepened toward the axillary fat, releasing and removing any scar tissue. Care must be taken to avoid injury to vital structures within the axilla.
- The TD or LT vessels are identified and preserved. Arterial and venous anastomosis is done end to end (ETE) to these vessels. The flap is placed in the pocket created.
- The axillary wound is closed over a suction drain. An implantable Doppler probe can be used for monitoring of anastomotic patency.

Medial Elbow

- The VLN flap is usually harvested with a skin paddle for this recipient site.
- A curvilinear skin incision is made on the medial volar elbow area at the level of the epicondyle.
- A pocket is created for the flap placement.
- The anterior recurrent ulnar artery and the basilic vein are identified and used for ETE anastomosis.
- The flap is inset loosely over nonsuction drains.

Table 3 Advantages and Disadvantages of Different Vascularized Lymph Node Transfer Recipient Sites

		Advantages	Disadvantages
Upper extremity	Axilla	Hidden incision/scar Scar tissue release Multiple recipient vessels	Buried flap requiring implantable Doppler probe for monitoring of anastomotic patency
	Elbow	Hidden donor site scar medially	Difficult dissection of recipient vessels Interruption with elbow flexion
	Wrist	Tension-free closure with skin paddle Ease of monitoring	Aesthetically displeasing skin paddle May require skin graft

Lower extremity	Groin	Hidden incisional scar Scar tissue release	Potentially deep dissection Buried flap requiring implantable Doppler probe for monitoring of anastomotic patency
	Posterior knee	Hidden incisional scar	Difficulty with positioning and microanastomosis
	Ankle	Tension-free closure with skin paddle Ease of monitoring	Aesthetically displeasing skin paddle May require skin graft Difficulty with footwear

Dorsal Wrist

- The VLN flap is usually harvested with a skin paddle for this recipient site.
- A transverse skin incision is used to create a pocket within which the flap can be partially inset.
- Arterial microanastomosis is done ETE to a superficial branch of the radial artery at the anatomical snuffbox.
- Venous microanastomosis is done ETE to a branch of the cephalic vein.
- The skin of the VLN flap is loosely approximated to the wrist skin over nonsuction drains to avoid compression.

Groin

- A skin paddle is usually not required for VLNT to this region.
- A vertically oriented linear skin incision is made at the medial groin beneath the inguinal ligament and just above the femoral pulse.
- Dissection proceeds toward the superficial femoral vessels, carefully preserving any skin perforators or branches of the greater saphenous vein.
- Any scar tissue is aggressively released and removed to create a pocket for the VLNT.
- Arterial microanastomosis can be done ETE to a branch of the superficial femoral artery or an adequate skin perforator or end to side (ETS) to the superficial femoral artery.
- Venous anastomosis can be done ETE to a branch of the accompanying femoral vein or a branch of the greater saphenous vein.
- The axillary wound is closed over a suction drain. An implantable Doppler

probe can be used for monitoring of anastomotic patency.

Posterior Knee

- For the rare occasions where the flap is to be placed at the posterior knee, a skin paddle is usually not required.
- A vertical skin incision is made medially just below the popliteal region.
- A pocket is created for placement of the VLN.
- Microanastomosis can be done ETE to the medial genicular branches or ETS to the posterior tibial vessels.
- Closure of the wound is done over a suction drain.

Dorsal Ankle

- The VLN flap is usually harvested with a skin paddle for this recipient site.
- A curvilinear incision is made on the dorsal ankle and deepened to the deep fascia.
- The superior and inferior skin envelopes are undermined to allow for the inset of the VLN flap.
- The dorsalis pedis (DP) vessels are identified and preserved for microanastomosis. This can be done in an ETE or ETS fashion for both the flap artery and vein.
- The flap skin paddle is then loosely inset into the skin pocket over nonsuction drains.
- A split-thickness skin graft may be required in cases in which the sides of the flap are too large to fit into the created skin pocket.

PEARLS AND PITFALLS

Assessment	■ Confirm the diagnosis of lymphedema and find out what therapy has been tried. ■ Exclude smoking, hypercoagulable states, or bleeding tendencies.
Donor site selection and harvest	■ The surgeon should be comfortable with harvesting from the chosen donor site. ■ Avoid harvesting the deep lymphatic chain of the thoracic and groin lymph node basins to prevent donor limb lymphedema.
Recipient site	■ Selection of proximal or distal recipient sites is dependent on

selection	surgeon preference, familiarity, and comfort; also, the area of the lymphedema, as well as discussion with the patient. ■ Release of scar tissue and the introduction of well-vascularized lymph nodes can promote angiogenesis.
Postoperative care	■ The vascularized lymph node transfer is a free flap, and monitoring should proceed accordingly. ■ Compression therapy should be continued postoperatively.

POSTOPERATIVE CARE

- Immediate postoperative care would include monitoring of the free VLNT recipient site for anastomotic patency and local wound complications, as well as monitoring of the donor site. Postoperative free flap care is unit dependent, but usually would include:
 - Hourly monitoring of the flap using clinical parameters for the skin paddle or implantable Doppler probe for buried flaps
 - Monitoring for development of hematoma at the recipient site
 - Monitoring for development of hematoma or lymphorrhea at the donor site. The latter can usually resolve conservatively with prolonged drain use
 - Prevention of thromboembolic problems using mechanical and chemical prophylaxis
 - The patient being kept NPO overnight for emergent flap take back if required
 - Early mobilization of patients on postoperative day (POD) 1
 - Early use of compression wrapping by trained lymphedema therapists
- Patients are usually discharged on POD 3 or 4.
- Follow-up would include regular clinic visits for monitoring for wound complications and results of the VLNT. The latter is preferably done using the same techniques as preoperative assessment of lymphedema severity.

OUTCOMES

- The VLNT is like any free flap, requiring time for neovascularization and lymphangiogenesis. Typically, objective measurement results are not seen until 1 year postoperatively. Patients often report symptomatic improvement almost immediately postoperatively, especially in cases where scar tissue has been excised and vascularized flap is placed.
- As the technique of VLNT gains increasing popularity, the number of studies reporting on its results are growing, with reduction rates of 0% to 100%.^{8,9,11–15} It is difficult to directly compare outcomes because there is a

wide range of donor and recipient sites, as well as severity of lymphedema.

- In a 20-year follow-up of 1500 cases of VLNT, Becker et al. reported a response rate of 98%, with 40% of patients with stage I and II extremity lymphedema achieving a 100% reduction rate.⁸
- In a study of 13 cases in which the supraclavicular VLNT was used for lymphedematous limbs by Akita et al., there was an improvement in lower extremity lymphedema index of 27% and a 54% improvement in lymphatic function.¹¹
- In a study of seven patients receiving submental VLNT to the lower extremity with a mean follow-up of 9 months, Cheng et al. reported significant reduction in the volume of the lymphedematous limb of 23% above the knee, 22% below the knee, and 27% above the ankle, with reduction in episodes of cellulitis.⁷
- In a study on 29 patients receiving simultaneous inguinal lymph node transfer with abdominal-based breast reconstruction with a mean follow-up of 11 months, Nguyen et al. reported a 79% symptomatic improvement and mean volume differential improvement of 10% at 12 months after reconstruction.⁹

COMPLICATIONS

- Complications of vascularized lymph node transfer
 - Lymphedema of donor site
 - Donor site pain
 - Lymphorrhea
 - Wound infection
 - Flap failure
 - Hematoma
 - Recurrence of lymphedema
- Complications of long-standing lymphedema
 - Infection
 - Sensory disturbance
 - Pain
 - Reduction in mobility
 - Reduced quality of life
 - Stewart-Treves syndrome (lymphangiosarcoma)

47 Fasciocutaneous Debulking of Extremity Lymphedema: The Charles Procedure

CHAPTER

Clifford C. Sheckter and Peter Johannet

DEFINITION

- Lymphedema is the accumulation of interstitial fluid and fibroadiposity in subcutaneous tissues as a result of dysfunction in the lymphatic system.
 - Compared with generalized edema, lymphedema by definition is caused by poor lymphatic outflow (compared to increased capillary leak).¹
- The disease is generally described in terms of primary vs secondary (ie, acquired) causes.¹
 - Primary lymphedema: congenital (less than 2 years), praecox (first to third decade of life), and tarda (greater than fourth decade of life).
 - Secondary lymphedema: malignancy, iatrogenic/surgery (most common in developed world), obesity, trauma, and infection/filariasis (most common worldwide).
- Although nonoperative treatment is the mainstay, each case should be evaluated individually. Surgical options including radical excision can offer significant improvement.

ANATOMY

- Lymphedema can occur anywhere in the body where lymphatics are present; however, the disease tends to be most problematic within the extremities and genitals.
- In the extremities, the lymphatic system courses within the soft tissue between the dermis and muscle fascia, and thus, the disease is confined to this area. Anatomic knowledge of the subcutaneous tissues and its contents is crucial for surgical treatment given many nerves run within or adjacent to muscle fascia.

- Lower extremity considerations:
 - Common peroneal nerve at fibular head
 - Sural nerve at posterior calf

PATIENT HISTORY AND PHYSICAL FINDINGS

- Generalized edema due to any underlying medical disorder (heart failure, renal failure, cirrhosis) or medication should be ruled out, given these causes are often reversible with proper medical management.
- Other limb-enlarging disorders should be considered including chronic venous insufficiency, deep venous thrombosis, congenital musculoskeletal limb discrepancy disorders, myxedema, and neoplasia.
- For lymphedema, determine primary vs secondary lymphedema based on the timing of onset, travel history (endemic filariasis), family history, and any personal history of injury, surgery, or radiation.
- Two-thirds of cases involve a single extremity; however, bilateral lymphedema is possible depending on the nature of injury (eg, pelvic lymph node dissection).²
- Examination of affected limb reveals supple tissue that often “pits” when gently pressed. Long-standing lymphedema causes skin changes including thickening of the dermis and thickening of the epidermis (hyperkeratosis).
 - The classic *Stemmer* sign is considered positive when the examiner is unable to pinch the skin on the affected side at the dorsum of second toe or second finger. The unaffected side will easily tent when gently pinched.³
- Measuring the affected limb is important both in terms of comparison to the normal side (if present) and assessing for improvement with anticipated therapy.
 - Volumetric measurements are the standard and can be achieved through either estimated circumference measurements or water displacement testing.
 - Circumference measurements, while easily accessible, can be plagued by poor interrater reliability.⁴
 - Water displacement testing, whereby the affected limb is submerged into large containers, is highly precise, albeit cumbersome. Volume in excess of 200 cc (compared to normal side) is considered diagnostic.⁴

IMAGING

- In general, imaging is not necessary for diagnosis with a convincing history

and physical exam. If there is uncertainty in diagnosis, tailored imaging can assist in excluding/confirming lymphedema. For surgical planning, some surgeons advocate for ultrasound to ensure competency of the deep venous systems.

- Ultrasound can evaluate for deep venous thrombosis.
- Computed tomography can evaluate for masses, lipodystrophy, venous thrombosis, and lymphedema with high sensitivity.
- Lymphoscintigraphy can help confirm the diagnosis through demonstrating both quantitative and qualitative impairment in trace.
- Indocyanine green lymphangiography can assist in delineating drainage patterns and is more often employed in the preoperative planning of lymphovenous anastomosis or vascularized lymph node transfer.

SURGICAL MANAGEMENT

- There are limited prospective studies comparing the different treatments of lymphedema, particularly surgical approaches. There is no defined period of waiting or algorithm for performing the different procedures.
- In general, nonoperative therapy is considered first line,¹ largely consisting of concentric extremity compression wrapping with or without mechanical compression. Surgery is usually reserved for those patients with the following characteristics:
 - Failed compression therapy
 - Recurrent soft tissue infection and/or cellulitis
 - Quality of life limitations such as pain, limited mobility, and psychosocial distress
- Operations are classified into two categories: physiologic and ablative.
 - Physiologic procedures involve three techniques
 - Creating new lymphatic anastomoses (lympholymphatic bypass).
 - Diverting lymphatic drainage into the venous system (lymphovenous bypass).
 - Autotransplanting lymph nodes from another part of the body (vascularized lymph node transfer). These techniques have their own chapter for further discussion on technique.
 - Ablative techniques involve directly removing tissue from the affected extremity and fall into two operations:
 - Liposuction

- Direct excision
- Direct excision is further characterized based on reconstruction modality: skin graft vs flap.
- Originally described by Sir Richard Henry Havelock Charles in the early 20th century from his proceedings in India, the surgery attributed to Charles involves radical debridement of all soft tissue superficial to skeletal muscle with placement of skin grafts from the excised tissue onto the limb muscle.⁵
- Staged excision: the lower extremity is excised in at least two operations staged 3 months apart. Thick tissue flaps are elevated 1 to 2 cm in thickness and then underlying soft tissue is excised down to muscle fascia. Flap skin edges are closed in a single dermal layer using permanent suture (eg, 3-0 nylon). This procedure shares eponyms including Homans, Sistrunk, and Thompson procedure.
- Though effective in terms of reducing limb volume, the Charles procedure unequivocally yields a poor cosmetic result, which some patients are willing to accept given the burden of lymphedema (**FIG 1**).
- Although the authors do not perform physiologic techniques for lymphedema, it is reasonable to attempt these procedures first, given the lower morbidity.
- More recent advances in lymphovenous anastomosis and vascularized lymph node transfer have shown some successes in reducing limb circumference, yet for patients with significant soft tissue redundancy, surgical excision still plays a significant role.
- Reports of combined lymph node transfer with a Charles procedure have been described.^{6,7}

FIG 1 • Preoperative photo of a lower extremity with severe lymphedema.

Preoperative Planning

- Volumetric measurements should be obtained as mentioned above. This allows for postoperative comparisons to demonstrate effectiveness.
- Ultrasound can be useful in assessing the deep venous system to ensure competency.

Positioning

- Majority of cases will only involve a single lower limb; however, even if multiple extremities are involved, only one extremity should be excised at any given time the significant morbidity of the procedure.
- The patient is positioned in supine with the leg prepped circumferentially and free. A sterile tourniquet will assist in accessing more proximal upper leg in the event this tissue is involved.

Approach

- This is an elective procedure and should only occur when the patient is free of infection (ie, cellulitis) and healthy. If soft tissue infection exists, there is higher likelihood of graft failure.
- General anesthesia due to pain and inability to use local anesthesia due to large surface area.
- Consider regional anesthesia blocks and even an epidural if feasible.

TECHNIQUES

■ Radical Fasciocutaneous Debridement With Split-Thickness Skin Grafts (Charles Procedure)

- After the limb has been prepped and draped in sterile fashion, all tissues planned for excision are marked and delineated.
 - Skin graft harvest trajectories are planned based on surfaces of greatest convexity with longest length (avoid anterior and posterior harvest over

knee and elbow).

- Skin graft donor site evaluation:
 - Evaluate the quality of the skin over the involved tissue planned for excision.
 - Lymphedema can cause hyperkeratotic skin, which is poor quality for skin grafting. In this event, split-thickness skin grafts may be harvested from a noninvolved area of the same leg (eg, upper thigh) or other sites such as contralateral leg, trunk, etc.
- The extremity is exsanguinated with Esmarch from distal to proximal, and the tourniquet is inflated at the proximal limb to 250 mm Hg.
- Split-thickness skin grafts are harvested with a dermatome device using the widest guard possible (usually 3–4 in.) with at least 0.012 to 0.015 in. of depth.
 - Thicker grafts yield better long-term results.
 - Sheet grafting (ie, nonmeshed) is the preferred method for cosmetic considerations, but this requires frequent graft rolling postoperatively, which may not be institutionally feasible.
 - Minimal meshing (such as 1:1.5) or graft fenestration can assist in seroma evacuation and graft take. However, graft meshing and expansion are not advised due to increased risks of secondary contracture and poor cosmetic result.
- Soft tissues are then excised down to muscle fascia using electrocautery.
 - Surgeons have the choice of preserving a thin film of adipose tissue overlying the fascia or excising the muscle fascia in entirety (**TECH FIG 1**).
 - Either way, avoid skin grafting directly on muscle fascia as this interferes with graft take.
- It is important to work systematically in excision.
 - It is often easiest to excise from proximal to distal given blood will run proximally when the leg is elevated.
 - Avoid excising distal to the ankle or proximal to the inguinal crease.
 - Take care to tie off or clip the large external veins of the leg (greater and lesser saphenous).
 - Also be careful to preserve the sural nerve and common peroneal nerve.
- Obtain meticulous hemostasis to increase likelihood of graft take.
 - Epinephrine-soaked sponges can assist in blood loss (even with

tourniquet).

TECH FIG 1 • Lower leg following adipofascial excision. Note that a layer of adipose tissue is preserved over the muscle fascia.

- Skin grafts are either stapled or sutured in place depending on surgeon preference.
- Skin grafts are covered with nonadhesive dressing such as N-Terface followed by a silver product (eg, Acticoat Ag) to prevent infection. This is then wrapped with Kerlix gauze and elastic ace wrap.
 - A knee immobilizer is placed in extension.
- Of note, skin grafting can be delayed for 1 week if there is concern for problems in graft take (ie, concern for serous drainage or infection).
 - In this scenario, skin grafts are banked, and negative pressure wound therapy is applied to the circumferential wound.⁸

■ Staged Excision^{9,10}

- Similar to the Charles procedure, the leg is prepped and draped circumferentially.
 - A vertical line is drawn on both the medial and lateral leg, dividing the leg into anterior and posterior halves.
- Skin is then incised vertically along the medial or lateral leg depending on which half is being excised.

- Adipodermal flaps are lifted in a suprafascial plane, preserving a cuff of adipose tissue (1–2 cm).
 - The elevation stops at the leg meridian.
- Soft tissues are then completely debulked from the adipofascial flap down to muscle.
- The anterior and posterior flaps are raised, and two drains are placed underneath.
 - The two flaps are secured to each other at midline using a single layer of 3-0 nylon sutures.
 - No deep sutures are used.
- Dressings are applied and the leg is wrapped circumferentially.

PEARLS AND PITFALLS

Hemostasis	■ When performing extremity adipofascial excision, use a sterile tourniquet, and limit runs to less than 2 hours. Let the tourniquet deflate to obtain hemostasis prior to placing skin grafts. Excise proximal to distal. Epinephrine 1:10 000 soaked sponges can assist in hemostasis.
Skin harvest	■ In general, it is easier to harvest the skin grafts prior to adipofascial excision given the difficulty in making a taught convex surface once the tissue is excised. ■ If excised donor leg skin is hyperkeratotic and poor quality, harvest skin grafts from contralateral leg or trunk.
Soft tissue excision	■ Leave a cuff of soft tissue around the ankle and knee (popliteal fossa, patella) to avoid exposing bone and vascular structures. ■ Be cautious when excising in the posterior calf and lateral upper lower leg to avoid the sural and common peroneal nerves.
Single vs staged	■ Consider staged excision in morbid patients who might not tolerate a complete leg debulking.
Cosmetic result	■ Appropriately set expectations with patients who these operations provide extremity debulking at the cost of poor appearance.

POSTOPERATIVE CARE

- As with any skin graft procedure, patients should be immobilized for 4 or 5 days to allow for graft take. This will almost always involve a hospital inpatient admission, which can allow for physical/occupational therapy assistance for mobility, and intravenous pain medication.
- All patients should be started on deep venous thrombosis prophylaxis such as subcutaneous heparin or low molecular weight heparin.
- Consider a 5-day course of intravenous antibiotics such as first-generation cephalosporin to prevent infection under the grafts.
- On postoperative day 5, all dressings are removed carefully with narcotic premedication. Wound care is targeted as needed to areas of healing difficulty.
- Prior to discharge, we recommend evaluation by occupational therapy and physical therapy for ambulation. Range-of-motion exercises are very important at the knee and elbow but are balanced against skin graft take. As soon as feasible, patients should be attempting full active range-of-motion exercises.
- Patients often require pressure garments for life to help prevent scar contractures. Lifelong follow-up with occupational therapy is advised.

OUTCOMES

- The largest series evaluating quality of life outcomes showed 63% satisfaction with limb-reducing surgery. 70% of all limb-reducing patients would opt for the surgery again.¹¹
- A common problem with the Charles procedure is poor appearance.
 - This results from the absence of subcutaneous tissues (ie, leg looks much thinner than normal leg).
 - There can also be a large step off at the junction of normal tissue and excised tissue from lack of contour between these sites (**FIG 2**).
 - Additionally, the skin grafts can become hyperkeratotic.

COMPLICATIONS

- These patients are at elevated risk of deep venous thrombosis given postoperative mobility limitations, diverting all venous blood into the deep system, and the significant inflammation from extremity excision.
- Suboptimal skin graft take is the most common complication that often results from local hematomas and seroma. Meticulous hemostasis along with meshed grafts can reduce this risk. Also, placing skin graft seems at lower tension points (avoiding joints) can ensure the highest graft take.
- Amputation has been reported.¹²

FIG 2 • Six months postoperatively with complete skin graft take. Note the hyperkeratotic appearance that is common following the Charles procedure.

48 Liposuction for Treatment of Lymphedema

CHAPTER

Dung Nguyen and Joseph Baylan

DEFINITION

- Lymphedema is lymphatic transport alteration/damage resulting in the accumulation of proteinaceous fluid in the interstitial compartment.
- Liposuction is the surgical removal of local excess fat from under the skin by vacuum suctioning using a cannula introduced through small skin incisions.
- Dry liposuction is performed without the use of local anesthetic or dilute epinephrine.
- Superwet liposuction uses a 1:1 mL ratio of infiltrate-to-aspirate for large volume aspirate removal, decrease blood loss, avoidance of lidocaine toxicity, and to minimize resultant fluid shifts.
- The pitting test refers to the amount of depression of the tissue (in millimeters) after the thumb is pressed as hard as possible on the extremity for 60 seconds.
- Tissue edema that harbors more fluid will have more pitting and tissue edema that is mainly hypertrophied fat or fibrous tissue shows little or no pitting.

ANATOMY

- Vital structures, such as neurovascular bundles and tendons that travel beneath the skin, can be injured during liposuction.
- The key anatomical areas to avoid during liposuction in the upper extremity are the axilla, antecubital region, and the wrist.
- In the lower extremity, liposuction at the femoral triangle, popliteal fossa, and ankles should be avoided.
- Subcutaneous fat is divided into superficial, intermediate, and deep layer. Distribution of each layer varies depending on anatomical location and liposuction is carried out in the intermediate and deep layer.

- Lymphatic capillaries are present in a subdermal plexus, which merge together into larger lymphatic vessels to form a complex network that carries lymph through the body. The lymph fluid enters a lymph node basin (ie, inguinal region, axilla) via several afferent lymph vessels where it is filtered and then transported toward the lymphatic ducts by efferent lymph vessels. Deep liposuction in the region of a lymph node basin can disrupt the lymphatic network and cause neurovascular injury.

PATHOGENESIS

- Long-term accumulation of lymph fluid causes chronic tissue inflammation that induces excess differentiation of fat precursors, fat hypertrophy, tissue fibrosis, and hyperkeratosis.
- Hypertrophied adipose tissue and tissue fibrosis are late signs of lymphedema.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Candidates for liposuction are those with late stage II (spontaneously irreversible) to stage III lymphedema (lymphostatic elephantiasis).
- These patients have been treated and are refractory to complex decompressive physiotherapy (CDPT) and compression garments.
- Physical examination:
 - Presence of nonpitting edema on pitting test.
 - Intact skin without open wounds.
 - No erythema or signs of infection.
 - Negative Homans sign, defined as calf pain with extension of the foot.
- Treatment contract:
 - The success of the surgery relies on the patient being reliable and compliant with compression garment use 24/7 for life.
 - Patients who wish to proceed with surgery are asked to sign a treatment contract before surgery.

IMAGING

- Dual-energy x-ray absorptiometry (DXA) is used to estimate the excess fat, muscle, and bone tissue in the lymphedema limb.
- From the DXA scan, measurements are made in grams and transferred to volumes by density, which is useful in estimating the amount of excess fat to remove in patients scheduled for liposuction.

SURGICAL MANAGEMENT

- Preoperative preparation:
 - Optimize nonsurgical therapy to reduce residual pitting edema in the tissue as much as possible prior to surgery.
 - Patients who have history of deep vein thrombosis (DVT) should get a baseline venous duplex study.
 - Appropriate preoperative evaluation of cardiopulmonary status is always indicated prior to any surgical procedure.
- The patient must be aware of potential complications to include bleeding, infection, pain, numbness and tingling, contour irregularity, and wound healing problems.
- Garments:
 - Two sets of garments are made to match the size of the normal limb (Juzo, class II 30–40 mm Hg): one set is given to the surgeon to put on the patient immediately after surgery; the other set, the patient will bring to the first postoperative clinic appointment.
 - Upper extremity garments include Juzo compression sleeve from wrist to axilla with shoulder strap and gauntlet.
 - Lower extremity garments include Juzo open toe compression stocking with adjustable waistband, toe cap, and biker shorts for compression of the thigh and hip area.
 - Donning device to aid in putting on and removing garments.
 - These garments are not sterilizable in the United States.

TECHNIQUES

■ Anesthesia

- General endotracheal anesthesia is preferred.
- Epidural or peripheral nerve blockade performed by a regional anesthesia team is optional for postoperative pain management.

■ Position

- The patient is placed in supine position, and the affected extremity is rested on a hand table or a leg raise, respectively (**TECH FIG 1**).

- During surgery, the extremity is raised with the help of an assistant to access the posterior surface of the limb.

TECH FIG 1 • Positioning of affected extremity prior to suction-assisted lipectomy.

■ Equipment

- Sterile tourniquet.
- Liposuction set to include 3 and 4-mm cannulas.
- Suction-assisted or power-assisted liposuction machine.
- Wetting solution containing 20 mL of 1% lidocaine, 1 ampule of 1:1000 (1 mg/mL) epinephrine and 8 mL of sodium bicarbonate (8.4 mEq/L) in 1 L of lactated ringers.

■ Details of Procedure

Video p7-c048

- Preoperative antibiotic should be given prior to incision.
- Piperacillin-tazobactam (Zosyn) is preferred for broad-spectrum antibacterial coverage, particularly in patients with diabetes or significant comorbidities.
- After general endotracheal anesthesia is established, the entire affected extremity is prepped and draped circumferentially in the usual sterile fashion.

Superwet Liposuction

- Begin with superwet liposuction of the upper arm or thigh. Wetting solution is used in the proximal limb to minimize bleeding because tourniquet is not possible in this location.
- The amount of tumescent infused is the same as the expected amount of lipoaspirate removed. This is determined preoperatively by DXA scan.
- Using a no. 11 blade, 5 to 8 stab incisions, 3 mm in length, are made circumferentially in the proximal half of the arm or thigh.
- Wetting solution is injected in 1:1 infiltrate: aspirate ratio into the subcutaneous tissues of the upper arm or thigh using an infiltrating cannula. Wetting solution is infused until skin turgor is present at the desired location.
- After 10 to 15 minutes, liposuction is performed in the proximal extremity circumferentially.
- We prefer a 4-mm liposuction cannula for large volume liposuction and a 3-mm liposuction cannula for fine tuning and contouring with suction set at a medium setting.
- Start with the limb at rest on the table and begin liposuction of the anterior,

medial, and lateral surfaces first.

- The limb is then raised and held by an assistant or placed on a leg raise (for a lower extremity) to allow liposuction of the posterior limb.
- Liposuction should be performed in segments to ensure maximal volume reduction at each location.
- Avoid liposuction of the axilla or the femoral triangle, respectively, to avoid inadvertent neurovascular injury.
- The end point is achieved when no fat is seen in the suction tubing and the skin is loose and hanging (**TECH FIG 2**).

TECH FIG 2 • Tumescence liposuction is performed in the proximal thigh.

Dry Liposuction

- Dry liposuction is used for the remainder of the limb to avoid bleeding and excessive swelling of the tissue. This is beneficial in the immediate postoperative period for easier placement of the compression garment. It also facilitates quicker recovery as there is less postoperative edema.
- Place a sterile tourniquet on the proximal extremity with an Esmarch used to exsanguinate the limb.
- The tourniquet should be inflated to 175 mm Hg in the arm and 275 mm Hg in the leg.
- 10 to 20 skin stab incisions, 3 mm in length, are then made along the length of the extremity using a no. 11 blade to gain access for circumferential liposuction.
- Using a combination of 3 and 4 mm cannulas, gentle circumferential

liposuction of the limb down to the wrist or ankle is performed to remove the excess fibrofatty deposits.

- Liposuction near the wrist and ankle should be done cautiously and with the smaller cannula to prevent excessive tissue trauma.

Irrigation

- All incision sites are irrigated with bacitracin solution (50 000 units/L) and cleaned.
- Apply antibiotic ointment to skin.
- With large volume of fat and lipoaspirate removed, there will be a noticeable reduction in the limb size and increased skin laxity in the extremity after liposuction is completed (**TECH FIG 3**).

Compression Garment Application

- The most challenging part of the operation is application of a clean custom compression garment, which is made preoperatively using the unaffected extremity as a sizer for the garment.
- We have found the most effective method is to be starting at the great toe and having an assistant lift the extremity while pulling force is being applied proximally to allow for the garment to span from the toes to the proximal thigh.
- Use of a donning device is also helpful to get the garment pass the hand or foot. The incisions are left open to drain through the sleeve.
- The tourniquet is then released once the garment is pulled to the level of the proximal thigh and secured.
- The entire extremity is additionally lightly wrapped with 6-in. Bias wrap to absorb the drainage.
- Total tourniquet time should be 120 minutes or less.
- There is typically minimal blood loss.

TECH FIG 3 • Liposuction is performed in segments. There is noticeable excess of skin envelope of the thigh and leg with reduction of large adipose volume. **A.** Dry liposuction is performed below the midthigh under tourniquet. **B.** Large volume of fibrofatty tissue is removed.

PEARLS AND PITFALLS

Patient selection	■ The ideal patient is one who has isolated nonpitting edema and can be compliant with 24/7 postoperative compression garment.
Approach	■ Use a systematic approach to liposuction by complete liposuction of each section of the extremity at a time. ■ Avoid liposuction at the axilla, the femoral triangle, or at the joints.
Tourniquet time	■ Allocate appropriate tourniquet time to each segment of the limb to avoid spending too much or inadequate time in one area. ■ Avoid liposuction at the axilla, the femoral triangle, or at the joints.
Compression garment application	■ Use a donning device to aid in garment placement.

FIG 1 • A. 69-year-old female with 5 years history of right leg lymphedema status post hysterectomy, lymph node dissection, and postoperative radiation therapy. Preoperative DXA scan calculates 6150 mL of edema in the right leg. **B.** Results 1.5 years after liposuction of 6300 mL of fat from the right leg. **C.** 68-year-old female with 10 years history of left lower extremity lymphedema status post radical hysterectomy, pelvic lymph node dissection, and postoperative radiation therapy for cervical cancer. Preoperative DXA scan calculates 2583 mL of edema in the left leg. **D.** Results at 1 year after 3300 mL of fat tissue removed by liposuction.

POSTOPERATIVE CARE

- Due to the large amount of fluid (sometimes in excess of 10 L, depending on severity of lymphedema) removed from liposuction, overnight observation is indicated due to potential fluid shifts and for pain control.
- Patients are kept on an IV antibiotic for 24 hours and are discharged with a 2-week course of cephalexin (Keflex) or trimethoprim-sulfamethoxazole (Bactrim DS) for penicillin allergic patients.
- Prescription for oral narcotics is given for pain control.
- Patients are encouraged to ambulate regularly.
- Compression garment is to stay on 24/7 and may change the Bias wrap as needed when soiled.

FOLLOW-UP

- First postoperative appointment is on postoperative day 3, and the patient is asked to bring the second premade garment set to clinic to be changed by the surgeon.
- Patients are instructed to change their garment daily thereafter and to wear it 24/7.
- Subsequent visits are every 3 months in the initial 1 to 1.5 years with each visit adjustments to the garments are made as the edema improves.
- Once complete reduction is achieved, the patient is seen annually.

OUTCOME

- In patients who can remain compliant with 24/7 compression garment use, complete volume reduction can be achieved after 1.5 years and maintained long term (**FIG 1**).

COMPLICATIONS

- Blistering, particularly at the ankles, for which Mepilex may be used to protect areas of sensitive skin as needed
- Infection
- Contour irregularity
- DVT
- Paresthesias

Section VII: Burns

49 Acute Management: Tangential Excision and Skin Grafting

CHAPTER

Yvonne Karanas

DEFINITION

- Tangential excision of a wound is defined as the sequential removal of eschar in thin layers until healthy tissue is reached. Punctate bleeding of the underlying wound bed signals the presence of viable tissue and the end point of excision.
- Tangential excision can be applied to any eschar of the skin in order to minimize the amount of tissue removed and preserve underlying viable tissue. It is most commonly used in burn surgery.
- This procedure was first described by Janecovic in the 1970s and has been adopted worldwide by burn and plastic surgeons.¹
- A split-thickness skin graft is a piece of skin removed from the body for the purpose of covering a wound in another location. The outer portion of the skin composed of the epidermis and some portion of the dermis is “split” from the remaining underlying dermis. Enough dermis is left in the “donor site” for re-epithelialization.
- A full-thickness skin graft is a piece of skin containing the “full thickness” of the epidermis and the dermis. Like a split-thickness graft, this piece of skin is removed from the patient and then transplanted to another site for wound closure or to add additional skin after contracture release. Unlike a split-thickness skin graft, no dermis is left behind so the wound must be closed primarily.

- Allograft is broadly defined as a tissue graft from another human being. In burn care and surgery, it refers to human cadaver skin used to provide temporary wound coverage.
- TBSA is Total Body Surface Area and refers to the amount of skin on the body that is burned.

ANATOMY

- Burns and traumatic injuries can result in partial-thickness and full-thickness injuries. These terms refer to the depth of the injury into the skin.
- Partial-thickness injuries involve the epidermis and some portion of the dermis.
- Full-thickness injuries involve the epidermis and the entire dermis and can even include the subcutaneous fat.

PATHOGENESIS

- Full- or partial-thickness skin necrosis may occur with trauma, burn injury, and severe soft tissue infections.
- There are approximately 486 000 burn injuries per year in the United States with 40 000 requiring hospitalization.²
- Worldwide, the magnitude of the problem is even greater.

NATURAL HISTORY

- Burns or traumatic injuries may initially appear as superficial injuries, but with time (72–96 hours), they may progress to full-thickness injuries.
- Judicious early debridement and serial wound care preserve all viable tissue while preventing wound infection.
- When the wound evolution is complete, areas of full-thickness and partial-thickness burns should be clearly delineated. Definitive surgical treatment may then be performed as needed.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Full-thickness injuries may present as white, yellow, or brown leathery, insensate areas that lack capillary refill. With time, they will progress to a black eschar (**FIG 1**).
- Partial-thickness injuries may be superficial with pink, moist, sensate tissue that has capillary refill.
 - Deep partial-thickness burns may be cherry red in color, lack capillary refill,

have decreased sensation, and may be dry. These burns are often described as “indeterminate thickness” as it is often unclear initially whether they will require surgical treatment or not.

- Burns and traumatic injuries may result in wounds that are a combination of different depths of injury (**FIG 2**).

FIG 1 • Lower extremity full-thickness necrosis from a severe soft tissue infection.

NONOPERATIVE MANAGEMENT

- Partial-thickness burns may be managed with wound care alone.
- In general full-thickness skin, necrosis requires surgical treatment. It may be managed conservatively in select situations, for example, small wounds that are less than 1% TBSA on the torso. A large burn is commonly defined as a burn greater than 20% TBSA.
- Wound care may be performed once or twice daily with silver sulfadiazine to soften and debride the eschar and prevent infection. Eventually the eschar will separate from the underlying wound bed; however, this process may take weeks or even months and lead to poor scarring and contractures.
- For large wounds, an expectant management strategy carries a high risk of wound infection.
- Surgical treatment remains the standard of care for large full-thickness wounds.

FIG 2 • A. Contact ankle burn with second-degree and third-degree components in a paraplegic patient. **B.** Flame burn to the thigh with mainly third-degree burns and small patches of second-degree burns.

SURGICAL MANAGEMENT

Preoperative Planning

- Equipment for Tangential Excision
 - Watson Knives (**FIG 3A**)
 - Weck/Goulian Knives (**FIG 3B**)
 - Epinephrine solution
- Equipment for Skin Grafting
 - Dermatome electric or air powered
 - Guards of different widths (**FIG 3C**)
 - Mineral Oil
 - Tumescent solution: 1 L crystalloid, 1 cc (1:1000) epinephrine, 0.25% Marcaine (30 cc)
 - Klein Infiltration Pump—allows for high-volume infusion of tumescent solution in a rapid fashion
- Tangential excision is performed using a variety of knives designed for this purpose, or a dermatome may be used.
- The choice of instrument is based on the location of the wound and the size and thickness of the eschar. Small burns or burns in delicate areas such as the hands, face, or feet are excised with a Weck knife. Larger, thicker burns on the extremities or trunk are excised with a Watson knife. The depth of the excision

can be set by adjusting the guard on the Weck knife or on the Watson knife itself.

- The Weck knife has three guards that can be placed over the blade to control for the depth of excision: 0.012, 0.010, and 0.008 in. The selection of the thickness of the excision is based on the surgeon's perception of the depth of the wound and the thickness of the skin in that region. The narrower guards of the Weck knife are used for less deep burns and areas of thin skin such as the dorsum of the hand, foot, or nose (**FIG 3D**).
- The Watson knife can be adjusted manually for thinner or thicker excisions. The knife is opened to its widest for large deep back burns, whereas more superficial leg burns would be treated with the knife only partially opened.

Video p7-c014_01

- Skin grafts are harvested using a dermatome which can be electric or air powered.
- A mesher is used to place holes in the skin, so that it can be stretched to cover a larger surface area (**FIG 3E**).

FIG 3 • A. Watson Knife. **B.** Weck knife with guards. **C.** Dermatome with 1", 2", 3", 4" guards. **D.** Weck knife with guard loaded on blade. **E.** Skin being meshed in a 2:1 fashion.

Positioning

- The patient is positioned to access the eschar and available donor sites. If necessary, the patient may be repositioned during the operation. For most lower-extremity wounds, the patient can be placed in the supine position.
- A plan to keep the patient warm during surgery should be formulated prior to the OR and implemented on arrival. Common strategies to maintain the patient's temperature include warming the room and all IV fluids, covering all nonoperative body parts with warm blankets and placing a heating pad or warming blanket under the patient.

TECHNIQUES

■ Tangential Excision

- Direct the blade of the knife at the skin in approximately a 30 degree angle to engage the eschar in the blade.
- Decrease the angle so that the blade is parallel to the skin through the remainder of the excision.

- Gentle pressure is applied as the blade is moved back and forth to slice off the eschar at a uniform depth. The motion of the blade is akin to playing the violin where the bow is slid back and forth across the strings.³
- Excise the most dependent portion of the eschar first, so that the bleeding will not obscure the remaining areas that require excision.
- This process should be repeated until the entire wound has healthy tissue present with punctate bleeding.

Video p7-c014_02

- Each area should be tangentially excised until a viable wound bed is obtained before moving to the next area. This will minimize blood loss and ensure that entire wound bed is adequately excised.
- After initial excision, the entire wound bed should be assessed to assure punctate bleeding is present throughout. If immediate skin grafting is planned, any areas of questionable viability should be excised again in the same method until the surgeon is satisfied with the appearance of the wound bed. If allograft is planned for areas of questionable viability, then these wounds can be left to see if they will survive. These areas can then be re-excised at the next surgical session as needed (**TECH FIG 1**).
- Epinephrine-soaked sponges are used for hemostasis followed by electrocautery to any bleeding that has not subsided.

TECH FIG 1 • Contact ankle burn after tangential excision and hemostasis.

- In the extremities, tourniquet control can be used while performing tangential excision.
 - A sterile tourniquet can be applied to the normal skin or even injured tissue proximally on the extremity.
 - The extremity is elevated and the brachial or popliteal artery compressed prior to inflation of the tourniquet. In general, exsanguination is not performed as the wounds may be contaminated or infected.
 - Excision then proceeds as outlined above. Given the inflated tourniquet, bleeding is not the end point of excision. The surgeon must become adept in assessing the underlying wound bed in the absence of bleeding. The dermal tissue should be glistening white and the fat a moist light yellow without hemorrhage. All thrombosed blood vessels should be excised. Once excision is completed, the tourniquet is deflated and the wound bed reassessed. Areas that do not bleed should be re-excised as outlined above.

■ Skin Grafting

- Split-thickness skin grafts are harvested using a dermatome.
- In general, 0.012-in. thickness is the standard setting for harvesting a split-thickness skin graft.
 - Thinner grafts may be used for large burns or when wound contraction is desired as is the case for fingertip injuries or plantar heel wounds.
 - Thicker grafts can be harvested for areas of functional importance and

where graft contracture should be minimized.

- The hands, face, feet, and genitalia are a few examples where thicker split-thickness grafts or full-thickness grafts would be utilized.
- Harvesting a skin graft is ideal when the donor surface is flat.
 - This can be achieved both by positioning the patient and manipulating the tissue with pressure and traction.
- For these reasons, the thighs are the preferred donor site for harvesting a skin graft.
- Local anesthetic can be injected prior to skin graft harvest for postoperative pain control.
- Other areas can be made smooth and flat by “tumescing” the underlying tissue similar to the technique used for liposuction.
 - This involves inflating or swelling the subcutaneous tissues with liquid.
 - A solution consisting of lactated ringers, local anesthetic, and epinephrine is injected into the subcutaneous tissue of the area of the planned harvest.
 - The amount of solution required is assessed for adequate “tumescence” by manual palpation to see if it is indurated and filled with fluid such that it is smooth and all bony prominences are now obscured.
 - Care must be taken to ensure the injection is subcutaneous and not within the deeper tissues.
- Tumescence is commonly performed over the back and chest where the ribs are palpable and the anterior lower extremities where the tibia is prominent.
 - If injected too deeply in the extremities, compartment syndrome could ensue.
- The tumescent solution also aids with hemostasis from the epinephrine effect and postoperative pain control from the local anesthetic.
- Mineral oil is applied to the skin and dermatome immediately prior to harvesting to allow the dermatome to slide more easily along the skin.
- Once the donor site has been prepared, the dermatome is turned on and applied to the skin at approximately a 45-degree angle.
- Light to moderate pressure is applied and the skin engaged by the dermatome.
- Once the graft is visible in the dermatome, the angle of harvest can be decreased to roughly 30 degrees.
- Under physician control, gentle forward pressure is applied to the dermatome along the entire length of the skin being harvested.

- The dermatome is then disengaged from the skin by angling it up akin to a “plane taking off from the tarmac.” The motor is engaged until the dermatome is off of the skin.

Video p7-c014_03

- After the skin grafts are harvested, topical epinephrine-soaked sponges can be applied to the donor site wound bed for hemostasis.
- Grafts can be kept on the technician’s table in moist saline soaked gauze until the surgeon is ready to apply them.
- The grafts can be applied as sheet grafts or meshed grafts. Sheet grafts contract less than meshed grafts, and their appearance is better. Grafts can be meshed 1:1 up to 9:1 as needed. Narrow mesh allows for fluid egress while minimizing the mesh appearance of the healed graft. Wider meshing allows for coverage of large wounds with minimal amounts of intact skin. The wider the graft is meshed, the longer the time to healing and the more wound contracture there will be. Widely meshed grafts can be difficult to work with as it may be challenging to identify the dermal side of the graft.
- Grafts should be placed with the dermal side in contact with the underlying wound bed. The surgeon should try to avoid having seams or joining areas over joints.

TECH FIG 2 • Meshed skin graft secured in place with staples.

- For the lower extremity, there are two techniques that facilitate grafting.
 - The first is to wrap the grafts circumferentially around the leg so that the seam is on the anterior surface of the leg.
 - The second is to place one long strip vertically on the posterior side of the leg.
- The remaining grafts can then be placed on the anterior, medial, and lateral sides.
- Both of these techniques minimize the amount of stapling or suturing that needs to be done to the posterior surface of the leg. Technically, this makes the surgery easier and allows it to proceed more expeditiously.
- The grafts can be secured with surgical staples (**TECH FIG 2**), sutures, and tissue glue or Steri-Strips/Hypafix (Smith & Nephew, London, UK) dressing tape.
 - Skin staples are the traditional method of fixation for large grafts.
 - Smaller grafts can be sutured in place obviating the need and pain of staple removal.
 - In recent years, Artiss fibrin sealant (Baxter, Westlake Village, CA) has become available and can be used to adhere grafts to the underlying wound bed.
 - Artiss is used in conjunction with staples, but these can be removed at the completion of grafting and when the Artiss has dried or alternatively a few critical staples may be left in place to be removed later.
 - Steri strips or other adhesive tapes can also be used on grafts that border

the normal skin.

PEARLS AND PITFALLS

Technique	■ If the Watson, Weck/Goulian blade is held in a too vertical position, it will incise the skin like a standard knife and can injure underlying structures. ■ Care should be taken over the Achilles tendon, malleoli, and the patella as overzealous excision will quickly result in tendon and bone exposure.
Tumescent technique	■ Care must be taken to ensure the injection is subcutaneous and not within the deeper tissues. ■ If injected too deeply in the extremities, compartment syndrome could ensue.
Excision	■ Adequate excision is the key to a successful outcome. It is critical that the surgeon ensure that all nonviable tissue has been excised prior to skin grafting.

POSTOPERATIVE CARE

- For larger grafts or in larger wounds, the grafts are covered with nonadherent gauze and silver impregnated dressings for antimicrobial protection. In the contaminated wound, the dressings are left in place for 72 hours, and then daily dressing changes are instituted. Early changing of bandages in these high-risk wounds helps identify infections and promote aggressive treatment to salvage skin grafts. Pseudomonas infection is a common culprit in these scenarios and can be treated effectively with mafenide solution-containing dressings. Smaller or less contaminated burns can be left in the postoperative dressing for 5 to 7 days, and then wound care can begin with any moisture-containing products. We commonly use Xeroform and Bacitracin. There is currently no conclusive data to support the use of systemic antibiotics after a skin graft procedure is performed.
- The vacuum-assisted closure (VAC) device can also be used to secure skin grafts during the early postoperative period. The VAC is placed in the operating room and left on for 5 to 7 days postoperatively depending on the surgeon's comfort with the cleanliness of the wound. After removal, standard daily dressing changes are instituted. The VAC is extremely helpful in getting

grafts to adhere to a wound bed that has concavities or irregularities. The VAC provides excellent fixation of the grafts so that movement of the extremity will not shear the grafts. This feature makes it an excellent choice for children who may not be compliant with immobilization instructions. In addition, the VAC provides a less painful wound environment often giving patients a break from the daily pain of wound care. In order to place the VAC, there must be a 1- to 2-in. border of the normal skin around the wound for tape placement (**FIG 4**).

- Grafts that cross joints should be immobilized with splints to prevent shearing of the grafts.
- Bolsters can be used to prevent movement of the graft and promote adherence of grafts in convex and irregular wound beds.
- Physical therapy with ambulation and range of motion is instituted on postoperative day 5 when the grafts should be adherent. For larger wounds and grafts, compression garments are worn once the wound is healed.

FIG 4 • VAC dressing in place.

FIG 5 • Six days after excision and grafting. The graft is pink and adherent.

OUTCOMES

- With experience, skin graft take should consistently be above 80% (**FIG 5**). Long-term outcomes from skin grafting depend on the severity of the injury, length of time to healing, and patient participation in therapy. Hypertrophic scarring, contractures, pigment changes, itching, and pain are long-term sequelae of the disease process and the treatment. Often, surgical release of contracture is necessary to regain full function after tangential excision and skin grafting.

COMPLICATIONS

- Graft loss (partial or total) remains the main complication.
- Causes:
 - Inadequate excision of the underlying wound bed
 - Hematoma
 - Seroma
 - Graft shear
 - Infection
- Contracture

Reconstruction of Contractures: Z-Plasty, Skin Grafting, and Flaps

50

CHAPTER

Xiangxia Liu

DEFINITION

- Scar contracture is the result of tightening of the skin during and after the wound healing process.
- The continuous and progressive contraction of the scar will cause the impairment of appearance and significant dysfunction of the affected area.
- In the lower extremities, especially around the knee and ankle joint, the contracture scar can cause significant restriction in movement and, therefore, should be treated as soon as possible.
- There are many surgical interventions to treat scar contracture, including Z-plasty technique for mild scar contracture, skin grafting for a larger area of skin defects after the releasing of the contraction, and a skin flap, especially around the knee and ankle joint area or when there are any bone, tendon, nerve, and blood vessel exposure.

ANATOMY

- The scar contractures in the lower extremities usually only affect the superficial fascia layer. Sometimes there will be exposed bone, tendons, nerves, and vessels after scar resection or revision.
- Lateral femoral circumflex artery (LFCA) arises from the deep femoral artery; it goes deep to the rectus femoris muscle and divides into three branches: the ascending, transverse, and descending branch. The Anterolateral thigh flap (ALT) is designed base on the perforator of the descending branch of LFCA (**FIG 1A**).
- Pedicled reverse-flow ALT flap is a useful tool to repair the defects around the

knee joint. The descending branch of LFCA will communicate with the arteries around the knee joint, which perfuses the pedicled reverse-flow ALT flap (**FIG 1B**).

- Perforator flaps based on the peroneal artery or posterior tibial artery (**FIG 1C**) are powerful tools to repair the defects around the ankle joint and the heel (**FIG 1D**).

FIG 1 • A. Arising from the profunda femoral trunk, the

lateral circumflex femoral artery (LCFA) gives three branches: ascending, transverse, and descending branch. The descending branch of LCFA travels deep with the space between the rectus femoris muscle and the vastus lateralis muscle. As traveling distally, it distributes the perforators, in most cases musculocutaneous perforators to the flap. **B.** The distal communicating artery between the descending branch of LCFA and the lateral superior geniculate artery is the anatomic basis for the reversed ALT flap. **C.** Through its course in the leg, the posterior tibial artery usually gives two to four major septocutaneous perforators; these perforators arise from between the soleus and the flexor digitorum longus muscle or between the flexor digitorum longus muscle and the medial aspect of tibial bone. The distance between the lowest perforator and the medial malleolus ranges from 3.5 to 8.2 cm.¹ **D.** The perforators of peroneal/fibular artery arise from between the soleus and the peroneus longus/brevis muscle. They are usually located within 2 cm from posterior border of fibular bone and are closer to the fibular bone proximally than distally.

IMAGING

- Preoperative radiography can help to distinguish simple and complex scar contracture, especially if an underlying skeletal abnormality is suspected.
- CT and MRI scanning play an important role in the evaluation of skin cancer.
 - An MRI can well identify the relationship among the tumor, calcaneus bone, and Achilles tendon in the case of Marjolin ulcer, an aggressive squamous cell carcinoma presenting in an area of chronic inflammatory scar tissue (**FIG 3**).

SURGICAL MANAGEMENT

Indications

- Z-plasty is designed to elongate a less contracted linear scar or to break a scar tension line.
- Skin grafting is an option when the primary closure is impossible and there is a lack of adjacent tissue for coverage.

FIG 2 • A. For a superficial nonhypertrophic scar on right arm with minimal contracture, the simple technique of Z-plasty will release the contracture scar and break the tension line. **B.** For this patient, skin grafting is needed to replace the unwanted hypertrophic scar on the dorsum of the right foot and to release the dorsal contracture of the second, third, and fourth toes. **C.** Both the Z-plasty and skin grafting are needed to fully release the contracture bands of the left ankle and foot.

- Flap should be applied when there is an exposure of the bone, nerve, blood vessel, and other tissues, which are unsuitable for skin graft.

Preoperative Planning

- Prepare the donor site for skin grafting.
- Use Doppler ultrasonography to confirm the perforator before the operation.
- Pathological study of the chronic ulcer in the scar area before the surgery is important.

Positioning

- The patient is placed supine on the operating room table with the entire lower extremity prepared into the field.
- The ipsilateral or contralateral thigh is prepared into the field in the event that

a split-thickness skin graft is needed.

- The scalp is another option for harvesting thin split-thickness skin grafts if the patients do not want to leave a visible scar on the donor site.

FIG 3 • A. Cauliflowerlike tumor on the right heel. **B.** MRI shows the tumor has a close relationship with the calcaneus bone and the Achilles tendon. A flap would be needed to cover this defect after tumor resection because there will be an exposure of both the bone and tendon.

- The groin is prepared in the event that a full-thickness skin graft is needed.
- A prone position will be helpful when the procedure is related to the posterior aspect of lower extremity.
- A lateral decubitus position will facilitate the exploration of the perforator of peroneal artery.

Approach

- Make the incision on the medial margin of ALT flap first as this will facilitate the exploration of perforators in the medial thigh in case that there is no perforator available in the lateral side.

TECHNIQUES

■ Z-Plasty

- Draw the center line on the part of the scar with the most contracture.
- Make a paired and paralleled limb line on each side of the center line

(**TECH FIG 1A**).

- Try to set the angle around 60 degrees between the center line and limb lines.
- Cut the skin along the designed lines.

TECH FIG 1 • **A.** Multiple Z-plasties marked on a contracture band. **B.** The flap is elevated superficial to the deep fascia. **C.** The paired Z-plasty flaps are transposed initially.

- Release the subcutaneous bands.
- Elevate the flap superficial to the deep fascia (**TECH FIG 1B**).
- Transpose the paired skin flaps (**TECH FIG 1C**).
- Trim the dog ears and overly abundant subcutaneous tissues.
- Place several sutures in dermal layer of the key areas.
- Close the wound accordingly.

■ Skin Grafting

Preparation of the Recipient Site

- Release the contracture bands of the scar (**TECH FIG 2A**).

- Make multiple zigzag incisions along the cutting edge of the wound to lessen the tension of the scar (**TECH FIG 2B,C**).
- Remove the scar tissues in the wound.
 - Control bleeding with bipolar electrocautery.
- Make a template of the defect.

Harvesting the Skin Grafts

- Use the tumescent fluid to flatten the surface of donor site and reduce bleeding.
- Use a power-driven (**TECH FIG 3A**) or freehand dermatome to harvest the split-thickness skin grafts from the thigh or scalp.
 - Choose the width and the thickness of the harvested grafts by adjusting the dermatome (**TECH FIG 3B,C**).
 - A simple way to assess the thickness is by passing a no.15 blade between the guard and the blade.
 - Install and lock a new disposable blade.
 - Make a 30- to 45-degree angle between the handle and the surface of the skin (**TECH FIG 3D**).
- Apply gentle downward pressure, and advance the machine slowly during the harvesting (**TECH FIG 3E**).
- Assess the thickness of the cut during harvesting by observing the grafts through the guard and the wound of donor site.
- Angle the machine upward, and lift off from the donor site when the harvest is complete.
- Cover the donor site with petroleum jelly gauze (**TECH FIG 3F**) or Melgisorb (Mölnlycke Health Care, Gothenburg, Sweden) combined with Mepilex (Mölnlycke Health Care, Gothenburg, Sweden).
- Put the grafts on petroleum jelly gauze with the dermal side facing up (**TECH FIG 3G**). A graft tends to fold over on itself, and this will help to keep it extended.

Placing and Securing the Grafts

- Place the grafts on the wound.
 - Keep the dermal side downward, and attach to the wound directly. The dermis has a shiny appearance and sticky sensation.
- Tailor the grafts to the wound and staple the key area.
 - Adding a suture at the tip of a small full-thickness skin graft and holding it

against the index finger can help to trim the grafts with scissor (**TECH FIG 4A,B**).

- Secure the grafts with suture, surgical staple, or fibrin glue (**TECH FIG 4C**), flushing beneath the grafts with normal saline before dressing.
- Place a petroleum jelly gauze directly on the grafts (**TECH FIG 4D**), and top that with a single layer of moistened gauze.
- Next, apply a circumferential wrap/tie-over bolster/negative pressure technique (**TECH FIG 4E**).
- A splint is applied to immobilize the extremity.

TECH FIG 2 • A. The contracture band is completely released. **B,C.** Zigzag incisions (*arrows*) are made along the cutting edge of the wound to minimize the scar contracture later on.

TECH FIG 3 • A. Aesculap model dermatome. **B.** Width is adjustable with 10 individual 8.0-mm cutting flaps. **C.** Cutting thickness varies from 0.2 to 1.2 mm in lockable 0.1 mm increments. The thickness reading indicates the maximal thickness the surgeon can harvest; grafts may be thinner depending on the pressure applied on the handle. **D.** The device is held at 30- to 45-degree angle between the handle and the surface of the skin. **E.** Split-thickness skin grafts being harvested from scalp. **F.** The donor site is covered with petroleum gauze. **G.** The harvested skin grafts are placed on the petroleum jelly gauze with dermal side facing up, which will facilitate placement in the wound.

TECH FIG 4 • **A.** A stitch is placed in the tip of the graft. **B.** Placing the graft on the dorsal of index finger and holding with thumb and middle finger helps with trimming. **C.** Graft in place and secured with staples. **D.** Petroleum jelly gauze is placed on the graft. **E.** Wrapped before splinting.

■ Skin Grafting Combined with Acellular Allodermal Matrix

- The recipient site is prepared by excising the scar as previously described.
- Acellular allodermal matrix is used to cover the defect (**TECH FIG 5A,B**).
- Split-thickness skin grafts are harvested and placed as described (**TECH FIG 5C**).

TECH FIG 5 • **A.** Premeshed acellular allodermal matrix. **B.** Placement of the matrix. **C.** Placement of split-thickness skin graft.

■ Flaps

Using an Expanded Flap to Repair a Contracture Scar

- Release the contracture scar.
- Harvest the expanded flap (**TECH FIG 6A,B**).
- Transpose and inset the expanded flap (**TECH FIG 6C**).
- Close the recipient and donor sites (**TECH FIG 6D**).

Using a Flap and Skin Graft

- In this patient, a pedicled reverse-flow ALT flap was used to reconstruct an ulcer of the scar in the knee area.
- The lesion is excised (**TECH FIG 7A,B**).
- The ALT (ALT) flap is designed, including the pivot point (**TECH FIG 7C**).
- The flap is elevated, rotated, and inset (**TECH FIG 7D–G**).
- Split-thickness skin graft is used to cover the donor site, and the recipient and donor sites are closed (**TECH FIG 7H**).

Using a Skin Flap to Repair a Heel Wound

- In this patient, lateral lower leg skin flap based on the perforator of peroneal vessel was used to repair a Marjolin ulcer on the heel.

Stage 1: Tumor Resection

- A 2 cm margin is marked.
- Dissection plan is under the deep fascia.
- The periosteum of calcaneus under the tumor is resected (**TECH FIG 8**).
- The wound is packed with iodine gauze.
- The second stage of reconstructive surgery is delayed until the negative margin is confirmed by the final pathology report.

Stage 2: Wound Repair

- Perforator investigation
 - Mark the head of the fibula, lateral malleolus, and fibula bone.

TECH FIG 6 • **A.** Scar contracture of the popliteal fossa with tissue expander placed on the lateral aspect of the thigh. **B.** Inferior-based flap design. **C,D.** Contracture scar excised and flap transposed.

TECH FIG 7 • **A.** Chronic ulcerative scar on the anterior aspect of the right knee with limited knee extension function. **B.** Excise the lesion completely. **C.** Design of the ALT flap and the marking of pivotal point. **D.** Flap monitor is used during the surgery. **E.** The ALT flap is incised and elevated. **F.** The

perforator. **G.** The flap is rotated into place to repair the defect. **H.** Skin graft is used to cover the donor site, and both sites are closed.

- Make an incision at the posterior margin of the flap, usually 3-5 cm posterior to fibula bone and between 6 and 15 cm above the lateral malleolus.
- Dissect under the deep fascia, from posterior to anterior toward the fibula.
- Identify any perforators coming out from the septum (**TECH FIG 9A,B**).
- Flap elevation and coverage
 - The incision is complete all around the flap.
 - Elevate the flap under the deep fascia.
 - Microclamp the perforators that are going to be ligated.
 - Release the tourniquet and observe the flap perfusion.
 - If flap perfusion is good, all the perforators, other than the selected one, are ligated.
 - If flap perfusion is not satisfactory, wait for about 15 minutes.
 - If perfusion is still not good, an adjacent perforator should be reopened and the perfusion reassessed until a satisfactory vascularity of the flap is guaranteed.
 - Rotate the flap and cover the wound (**TECH FIG 9C**).
- Donor site closure with skin grafting
 - Temporarily staple the flap to the margin of the wound, and measure the defect of donor site and the uncovered one.
 - Use power-driven dermatome to harvest the split-thickness skin grafts from the thigh.
 - Tailor the skin grafts to the wound and staple it (**TECH FIG 9D**).
 - Soft bulky dressing is put on the flap.
 - The distant part of the flap is exposed without dressing for flap monitoring.

TECH FIG 8 • A. Cauliflowerlike tumor on the right heel. **B.** The defect after the excision surgery.

TECH FIG 9 • A. One week after the initial excision surgery, a flap based on the perforator of peroneal artery is elevated. The blue dot shows the location of

the perforator. **B.** The perforator is seen arising between the soleus and peroneus brevis muscle. **C.** Flap rotation to cover the area of the Achilles tendon and calcaneus bone exposure. **D.** Donor site is covered by split-thickness skin graft. No active suction drainage is placed around the perforator.

PEARLS AND PITFALLS

Z-plasty

- Flap angle of 60 degrees will get maximal elongation (**FIG 4**).
- The angles should set up to be a little more than 60 degrees when there is a severe contracture of the scar line because as the contracture scar is released, the angles tend to go sharper than designed.
- Place the lateral limbs parallel to the line in which the new central line will lie.
- Always cut the center line before cutting the limb.
- In scarred tissues, raise a thick flap that includes a layer of subcutaneous tissue to ensure adequate blood supply.
- In multiple Z-plasty, the designed flaps may not always interdigitate to each other perfectly.

Skin grafting

- Make sure the defect is suitable for skin grafting before harvesting the graft.
- Kirschner wire fixation can help in patients with severe contracture deformity (**FIG 5**).
- The formula for tumescent fluid: 500 mL lactated Ringer solution plus 1 mL/1 mg epinephrine.
- Harvest 5%–10% more grafts than the template because the graft always tends to shrink.
- Always keep the grafts moist.
- It is important to keep the dermal side downward and attach to the wound directly. False orientation will lead to a complete necrosis of the grafts.
- Inadequate wound preparation always contributes to the failure of skin grafting.

Flaps

- Locate the perforators by using ultrasound Doppler preoperatively to help dissection during the surgery.
- Always explore the perforator under tourniquet control before elevating

the flap.

- Modify the design of the flap based on the perforators discovered during surgery.
- Although the perforators that are identified by ultrasound preoperatively may be good, sometimes better ones will be uncovered during the dissection.
- Placing a drain near the perforator that can compress the vessel or putting excessive compression over the pedicle of the flap will jeopardize the blood supply of the whole flap.

FIG 4 • A. The angle of a Z-plasty should be about 60 degrees, as shown on this congenital constriction ring of right lower leg. Black = center line; blue = limb lines. **B,C.** Immediately after Z-plasty, the constriction ring had been excised.

FIG 5 • A. Dorsal contracture of the second, third, and fourth toe of the right foot. **B.** Placement of K-wire fixation before the placement of acellular dermal matrix and split-thickness skin graft.

POSTOPERATIVE CARE

- A soft dressing is applied to the wound of Z-plasty. There is no need to restrict the mobility of patients with simple Z-plasty reconstruction.
- Dressing is applied to provide compression over the skin graft site.
 - Tie-over bolster technique or negative pressure wound therapy may be helpful to increase the take rate of the grafts.
 - The lower leg and foot cast or splint should be applied if the skin graft site is near to the knee or ankle.
 - The cast or splint can be removed after about 2 weeks. If the tie-over bolster technique was applied, remove the bolster carefully to avoid the shear injury to the grafts.
- After the flap surgery, mark the location of flap's pedicle where the perforators enter the flap and avoid pressure over it.
 - Postoperative flap monitoring is vital for the reconstruction.
 - Capillary refill time is still a secure and practical way to monitor the flap.
 - A cast or splint on the surgical site would be helpful if there is a skin grafting at the same time.
- The postoperative scar care, such as pressure garments and silicone gel, should be applied to all patients for a better functional and aesthetic result.

OUTCOMES

- Outcome photos for the cases in this chapter are shown in **FIG 6**.

COMPLICATIONS

- Potential causes of skin graft loss

FIG 6 • Case outcomes. **A.** Two-year follow-up of split-thickness skin grafting in the patient in **TECH FIG 4**. **B.** One-year follow-up of skin graft combined with acellular dermal matrix in the patient in **TECH FIG 5**. **C.** Six-month follow-up of expanded thigh flap to repair a contracture scar in the patient in **TECH FIG 6**. **D.** One-year follow-up of an ALT flap in the patient in **TECH FIG 7** shows a pliable flap and full extension of the knee. **E.** Three-month follow-up of the patient in **TECH FIG 9**, who underwent skin flap repair of a Marjolin ulcer on the heel. **F.** Ten-year follow-up of the patient in **FIG 4**, who underwent Z-plasty for a congenital constriction ring.

FIG 7 • **A.** Epidermolysis of skin graft. **B.** Partial necrosis of skin graft caused by hematoma underneath. **C.** The distal part of an expanded flap became necrotic.

- Infection
- Hematoma/seroma
- Poor vascularization
- Irradiation

- Other complications
 - Epidermolysis of skin graft (**FIG 7A**)
 - Partial necrosis of the skin grafts (**FIG 7B**)
 - Partial necrosis of an expanded flap (**FIG 7C**)

ACKNOWLEDGMENTS

The author thanks Drs. Xunxun Lin and Wenjun He for their help in preparation of **FIG 1**.

51 Soft Tissue Reconstruction with Propeller Flaps

CHAPTER

Adam Jacoby, John T. Stranix, and Pierre B. Saadeh

DEFINITION

- Propeller flaps represent one of the most recent technical advances in perforator flap dissection.
- Propeller flaps are especially useful alternatives to microvascular free tissue transfer when reconstructing distal lower extremity defects.
- The perforator propeller flap can provide soft tissue coverage on all parts of the body despite its original and most common use for lower extremity defects. Its adipocutaneous composition and ability to be rotated up to 180 degrees provide an excellent source of thin pliable tissue along with a faster and relatively simpler dissection compared with free flap harvest.
- To be considered a “propeller,” the flap must rotate between 90 and 180 degrees around its perforating vessels.

ANATOMY

- Propeller flaps can be classified based on pedicle anatomy, either the type of pedicle supplying the flap or the pedicle position.
 - Island propeller flaps are skeletonized along the perforator vessels and allow up to 180 degree rotation with relative protection from pedicle kinking.
 - Nonskeletonized propeller flaps can be either skin- or muscle-based pedicled flaps where the dominant perforator is not skeletonized. Although operative times are shorter and there is less risk of perforator injury from dissection with nonskeletonized flaps, pedicle kinking is more likely—especially when rotated greater than 90 degrees (**FIG 1**).
- Propeller flaps can also be classified as a central axis propeller (pedicle in the middle of the flap) or an eccentric axis propeller (at its periphery).

- The arterial supply to the lower extremity is provided by the posterior tibial, anterior tibial, peroneal, descending genicular, and popliteal arteries with its venous supply largely mimicking the arterial network.
- Perforators of the lower extremity form five vascular territories, separated by four organized rows of perforators originating within the intermuscular septa of the leg (**FIG 2**). Anterior tibial artery perforators are most often the smallest caliber.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Lower extremity defects are often caused by trauma, burns, or tumor extirpation. The defect size, depth, and location must be evaluated in addition to the surrounding skin quality. Additionally, exposed hardware (in the presence of orthopedic injuries), the bone, and the tendon must be taken into consideration when planning a durable reconstruction.
- If the patient has severe peripheral vascular disease or insulin-dependent diabetes, atherosclerotic disease may prevent adequate inflow to the flap.
- If the defect is from tumor ablation, the patient may undergo perioperative chemotherapy or therapeutic irradiation.

IMAGING

- While computer tomographic (CTA) or conventional angiography is not required for surgical planning, CTA may demonstrate the presence and location of larger caliber perforators, which can aid in flap design.

FIG 1 • Diagram of different pedicle dissections in propeller flap harvest; **A.** subcutaneous propeller flap, muscle-based propeller flap (**B**), and “true” skeletonized propeller flap (**C**). Note the relative bulkiness of the subcutaneous and muscular pedicles, placing them at higher risk for pedicle kinking with greater than 90

degrees of rotation.

SURGICAL MANAGEMENT

Preoperative Planning

- Unless contraindicated, general anesthesia with endotracheal intubation is preferred for these cases as the meticulous perforator dissection benefits from muscular paralysis intraoperatively. We routinely utilize preoperative Doppler detection of perforators for flap planning; however, it is not always necessary.
- Although we find the use of a Doppler to be helpful, perforator detection may be confounded by superficial feeding blood vessels. In the setting of normal lower extremity arterial anatomy, intermuscular perforators are reliably found during intraoperative dissection, making preoperative Doppler identification a useful adjunct rather than a requirement.
- If a Doppler is used, the length and width of the flap can be designed as follows:
 - The distance between the marked perforator and most distal aspect of the planned defect is measured; this distance is then transposed proximally, and 1 to 2 cm is added to determine the total length of the flap.
 - Half a centimeter is added to the anticipated defect width (to allow for contraction of the flap) to determine flap width (**FIG 3**).

FIG 2 • Schematic of lower extremity vascular territories and their feeding vessels. ATA: anterior tibial artery, PTA: posterior tibial artery, PA: peroneal artery. Small dots represent location of reliably found septocutaneous perforators within each angiosome.

Positioning

- Location of the anticipated defect and dominant perforator dictate operative positioning as propeller flaps are useful in head-to-toe reconstruction.
- For propeller flaps supplied by the posterior tibial artery system, supine positioning is used with the hip in abduction and leg externally rotated. Propeller flaps based off the peroneal system also require supine positioning, but a “bump” is placed under the ipsilateral hip. The hip and knee are then flexed and internally rotated.
- For all flaps below the hip, a circumferential prep of the entire extremity is

used routinely to ensure full visualization and allow intraoperative repositioning as needed. This also facilitates split-thickness skin graft harvest if required for donor site coverage.

- For gluteal, sacral, or lumbar flaps, the patient is placed in prone position. The patient is sterilely prepped and draped widely—typically from the midthoracic region to the upper thighs.

FIG 3 • The distance between the marked perforator (red star) and most distal aspect of the planned defect is measured (distance a). This distance is then transposed proximally, and 1 to 2 cm is added to determine the total length of the flap (length = $2a + 1-2 \text{ cm}$). Half a centimeter is added to the anticipated defect width (to allow for contraction of the flap) to determine flap width ($b + 0.5 \text{ cm}$).

Approach

- When designing a propeller flap, it must be kept in mind that a skeletonized perforator can be rotated maximally 180 degrees around itself, whereas subcutaneous and muscle pedicled propeller flaps only allow for 90 degree rotation without kinking (see **FIG 1**).
- As mentioned above, though preoperative Doppler use may help identify perforator locations, for skeletonized perforator flaps, the target perforator is only chosen after a suprafascial or subfascial dissection allows for visual inspection and confirms palpable pulsatility. An exploratory incision must be planned for adequate perforator exposure and examination which should not violate bail-out local flaps or an adjacent propeller flap supplied by a different perforator.
- Predicted preoperative flap outlines (based off on-table Doppler examinations) often change after intraoperative dissection locates the dominant perforator.
- Maximum size has yet to be described, but there are case reports of a 22 × 8 cm peroneal artery perforator propeller flap^{1,2} and a 19 × 13 cm posterior tibial artery propeller flap¹ based off one perforator. Perforators off the anterior tibial artery are generally the smallest caliber in the lower extremity and require smaller flap designs accordingly.
- Skin grafting may be required for donor site coverage; however, in our experience, primary closure is often achievable when defects are lesser than 6 cm in greatest width.
 - Although primary donor site closure is ideal, it should not be done under excessive tension that could potentially compromise the flap or lead to wound breakdown. A small skin graft is preferable to either of those potential consequences.

TECHNIQUES

■ Islandized Propeller Flap

- The defect with its appropriate margins is first defined (**TECH FIG 1A**).
- A Doppler is then used to locate dominant perforators (most often originating from the intermuscular septa).
- The length between the perforator and most distal aspect of this defect is

transposed proximally (1 cm is usually added) to determine total length of the flap whereas 0.5 cm is added to the defect width to calculate flap width (**TECH FIG 1B**).

- If the defect is below the hip, a thigh tourniquet may be applied. The leg is elevated for 1 minute prior to tourniquet inflation, but not completely exsanguinated in order to assist with visual identification of perforators.
- After completion of the flap design, a no. 15 blade is used to incise only one edge of the planned flap.
- Using loupe magnification and microsurgical dissection technique, exploration of perforators is then carried out in either the supra- or subfascial plane.
- We recommend using 3.5× loupe magnification for optimal perforator visualization in addition to a subfascial approach as we find this dissection plane is often faster and safer.
- In either the supra- or subfascial plane, perforators are identified. The ideal perforator is large, associated with two venae comitantes, and has a strong palpable pulse (**TECH FIG 1C**).
- The tourniquet is released, allowing assessment of the vessel's pulsatility.
- Spasm may prevent a pulse from being palpable; it can take up to 10 to 20 minutes after tourniquet deflation for pulse appearance.
- To protect against vasospasm, papaverine or 4% lidocaine is used liberally on preserved perforators.
- If two or more perforators have characteristics capable of flap sustainability, they can be alternatively clamped after the tourniquet is released to determine the optimal source vessel.
- Once the ideal perforator is located, the perforator foramen is then enlarged to allow for 2 cm clearance of fascial strands and muscular side branches (to prevent pedicle kinking during rotation) (**TECH FIG 1D**).
- After complete skeletonization, the flap design is adjusted to optimize the perforator location for rotation into the defect. The remaining edges of the flap are then incised, and dissection is carried out in the same plane until the flap is fully elevated and isolated on the single perforator.
- The flap can be rotated up to 180 degrees (see **TECH FIG 1D**) clockwise or counter clockwise (whichever direction provides greatest coverage with the least amount of pedicle kinking).
- After rotation around the pedicle is complete, the edges of the flap are

evaluated for healthy bleeding, and the distal flap is inspected for any signs of venous congestion.

TECH FIG 1 • **A.** Defect with exposed tibia. **B.** The flap is marked adjacent to the defect. **C.** Subfascial dissection reveals a dominant perforator. **D.** The pedicle is appropriately skeletonized around the dominant perforator and rotated 180 degrees. **E.** Flap inset and closure can often be achieved without skin grafts and closed suction drains unless the donor site is too large to be closed primarily as seen above.

- Satisfied with flap viability, inset occurs in the following sequence:
 - Secure the flap in place with two to four deep (fascial) sutures (often 3-0 PDS), equally spaced along the perimeter of the flap.
 - If a closed suction drain is necessary, it is positioned away from the vascular pedicle.
 - Superficial, interrupted, skin sutures (3-0 nylon) complete the flap's inset.
 - Loose inset is preferable as postoperative swelling may cause venous congestion and/or ischemia.
 - If the donor is not amenable to tension-free primary closure, a skin graft is harvested for coverage (**TECH FIG 1E**).
-

■ Nonskeletonized Propeller Flaps

- The design and execution of a nonskeletonized propeller flap is similar to its islandized counterpart, and the initial steps are similar, but the dissection is significantly faster; the differences in planning and techniques will be outlined here.
- The defect is first defined (either by tumor ablation or adequate wound debridement) and converted into a circular shape (**TECH FIG 2A**).
- A Doppler is then used to locate dominant perforators within 360 degrees of the defect.
- Note that when planning these nonskeletonized flaps, tissue can only be rotated a maximum of 90 degrees to avoid pedicle kinking (see **TECH FIG 2C**).
- Once the ideal perforator is located, the flap can then be designed. Depending upon the degree of rotation, flap length must be greater than defect width as the effective length of a flap becomes shorter with increasing rotation (**TECH FIG 2B,C**).
- A subfascial plane is again preferred for dissection. After rotation around the pedicle is complete, the edges of the flap are evaluated for healthy bleeding, and the distal flap is inspected for any signs of venous congestion.
- Satisfied with flap viability, inset occurs in the following sequence:
 - Secure the flap in place with two to four deep (fascial) sutures (often 3-0 PDS), equally spaced along the perimeter of the flap.
 - If a closed suction drain is necessary, it is positioned away from the vascular pedicle.
 - Superficial, interrupted, skin sutures (3-0 nylon) complete the flap's inset.
- Loose inset is preferable as postoperative swelling may cause venous congestion and/or ischemia.
- If the donor is not amenable to tension-free primary closure, a skin graft is harvested for coverage (**TECH FIG 2D**).

TECH FIG 2 • **A.** Defect and surrounding indurated tissue around the medial malleolus. **B.** The defect is created and the anterior flap is raised; the perforators perfusing the flap are left in the subcutaneous tissue and not skeletonized, making a relatively easy and fast dissection. **C.** When the dominant perforator is not skeletonized, maximum rotation is 90 degrees. **D.** If the defect is too large for primary closure, a skin graft may be used.

PEARLS AND PITFALLS

Incision placement

- Incisions should not violate adjacent bail-out options or alternative flaps.
- Initial exploratory incision should be as wide as possible so multiple perforators can be evaluated.

Perforator choice

- Visual and manual inspection is key to determining the optimal perforator.
- When possible, the chosen perforator should be at least 2 cm away from the most proximal aspect of the defect.
- Venae comitantes are at high risk of kinking during rotation

and fascial attachments must be cleared liberally.

- Perforators from the anterior tibial artery are usually the smallest in the leg and allow for the smallest flap dimensions.

Flap inset

- After dissection of the flap is complete and only attached by the skeletonized perforator, the tourniquet should be released to assess viability and perfusion.
- Vasodilators (lidocaine, papaverine) should be used liberally.
- Before inset, the flap should be rotated clockwise and counterclockwise to determine which way causes less kinking.
- Excessively tight closure can result in vascular compromise with subsequent partial or complete flap loss.

Contraindications

- Poorly controlled diabetes
- Peripheral vascular disease
- Peroneal artery and its perforators are most likely to be resistant to atherosclerotic disease and can still be used in diabetic and peripheral vascular disease patients.

POSTOPERATIVE CARE

- Patients should rest with the reconstructed extremity or body part elevated above heart level where possible.
- A gentle ACE wrap can be applied to lessen postoperative edema but should not be too tight to cause ischemia; a small window should be cut in the dressing (especially over the most distal aspect of the flap) to monitor perfusion and congestion.
- An orthotic boot or plaster posterior slab can be applied to maintain optimal positioning for pressure offloading.
- Skin sutures can be removed 10 to 14 days after surgery.
- If a skin graft is placed over the donor site, a VAC dressing bolster should be applied over the skin graft and removed 5 to 7 days postoperatively.

OUTCOMES

- Complication rates of propeller perforator flap are close that of free flaps.^{3–5}
- Most flap loss is related to venous congestion from pedicle kinking.^{4,5}
- In the case of flap loss, outcomes are usually better than free flap loss as most often only the superficial portion of the propeller flap becomes necrotic, leaving vital structures covered by deep portions of the flap.^{2,4}
- If congestion or ischemia is suspected, flap can be deinset and derotated, or a

venous microsurgical anastomosis can be performed if feasible.

COMPLICATIONS

- Distal tip necrosis
- Pedicle kinking
- Venous congestion
- Flap loss
- Contour deformities, scarring
- Hematoma
- Infection

PART 8

Pediatrics

Section I: Cleft Lip

1 Anatomical Subunit Repair of Unilateral Cleft Lip

CHAPTER

David K. Chong and Kathryn V. Isaac

DEFINITION

- Cleft lip is a congenital malformation in embryonic development leading to discontinuity of the upper lip. The cleft may be:
 - Complete or incomplete
 - Bilateral or unilateral
- Cleft lip may occur in isolation or in combination with a cleft palate. It may occur as part of a syndrome or in the absence of associated anomalies.
- A cleft lip has an associated cleft nasal deformity with characteristic features varying in severity depending on the type of cleft lip, width of the cleft, and presence of associated cleft palate.
 - The cleft lip nasal deformity affects the skeletal, cartilaginous, and muscular framework.

ANATOMY

- During the 5th to 7th weeks of gestation, cleft lip occurs as a failure of complete union of the medial nasal process and the maxillary prominence.
- Clefting occurs through the skin, muscle, and mucosa of the labial and nasal structures.
- The cleft of the lip distorts and/or disrupts several important anatomic structures.
 - Muscles
 - Orbicularis oris (pars marginalis and pars peripheralis)

- Pars alaris, depressor alae nasi
- Upper lip
 - Cutaneous lip: philtral columns, central dimple, cutaneous roll
 - Red lip: Cupid's bow, vermillion, mucosa
- Nose
 - Nasal floor, alar base, nasal cartilages, septum, columella

PATHOGENESIS

- The etiology of cleft lip is genetically complex and is due to multiple genetic and environmental risk factors.
 - Most cases are sporadic, but some are familial, X-linked, or autosomal dominant. Familial history of clefting is an important risk factor.
- Cleft lip and cleft lip with cleft palate are considered variants of an entity that differ in severity.
 - The environmental risk factors associated with clefting include maternal smoking, infection, poor nutrition, teratogen exposure (alcohol, phenytoin, valproic acid, retinoic acid), and advanced paternal age.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Diagnosis of a cleft lip is made by prenatal ultrasonography, by MRI, or by physical examination at birth. Detailed assessment is made of the child's breathing, feeding, growth, and development.
- Assessment of growth and weight is key to identify and monitor feeding difficulty and use of feeding aids (Haberman/Pigeon teat).
- The plastic surgeon should define the cleft lip type according to the anatomic structures involved, laterality, width of the cleft, and presence/absence of a cleft palate.
- Also, the child should be assessed for associated anomalies suggestive of a syndrome—craniofacial dysmorphism, airway compromise, cardiac defects, ocular and auricular abnormalities, and musculoskeletal anomalies. A genetics referral is suggested if suspicious of a syndromic etiology.

DIFFERENTIAL DIAGNOSIS

- Syndromic cleft lip with or without cleft palate
 - Van der Woude syndrome
 - Gorlin syndrome
 - CHARGE syndrome

- Ectrodactyly-ectodermal dysplasia-clefting
- Brachio-oculofacial syndrome
- Kabuki syndrome
- Kallmann syndrome

SURGICAL MANAGEMENT

- Cleft lip repair is ideally performed at age 6 months because the landmarks are larger and easier to identify.
- The principles of the anatomical subunit repair enable the surgeon to formulate a plan for the predictable and successful closure of any type of cleft lip.¹
- The labial cleft closure is designed, measured, and determined prior to skin incision. The operation is the execution of a formulated plan. This eliminates the potential of compromising landmarks and removes the fear of under-rotation, as well as lip height or length discrepancies.
- With this repair, the most visible part of the scar lies along the anatomical subunits, and the labial elements are perfectly matched in length to create an optimal continuity of vermilion, cutaneous lip, and alar-labial junction.
- Rotation of the labial elements is achieved by:
 - Skin triangle above the cutaneous roll
 - Muscle repair
 - Mucosal release
- Risks of the procedure are scar deformity, nasolabial asymmetry and/or deformity, wound dehiscence, and infection.
- The main objectives of the cleft lip repair are to (1) separate the nasal and oral cavities; (2) restore lip continuity and continence; (3) reconstruct a functional labial sphincter for facial expression, speech, and feeding; (4) and restore aesthetics of the labial and nasal subunits.
- The main steps of the procedures are as follows:
 - Marking key landmarks and designing closure of labial elements based on pre-incision measurements
 - Medial lip element release of skin, muscle, and mucosa to adequately balance the Cupid's bow, then composite elevation of lateral lip elements to insert into the created "jigsaw"
 - Restoration of muscle continuity
 - Closure of the mucosa
 - Closure of the nasal floor
 - Skin and vermilion closure

- Nasal correction with suture techniques
- In discussing this repair, the language used in Millard's description of the rotation-advancement cleft lip repair will be used.² The application of this language will help to clarify and describe this technique for surgeons who have adopted the Millard technique or modifications of it.

Preoperative Planning

- If the child has a cleft lip and cleft palate, dentofacial orthopedics are utilized for aligning the cleft maxillary arches and improving the nasal deformity (lower lateral cartilage shape and position and septal cartilage alignment). The device is discontinued prior to the cleft lip repair.

Positioning

- The patient is positioned supine with the neck neutral and head stabilized in a head ring.
- The surgeon must have the ability to freely examine the face from all angles throughout the procedure to ensure that three-dimensional balance is achieved. Corneas are protected with transparent tape to use the plane and position of the eyes in the surgical field as an aid to assessing labial and nasal symmetry. The transparent tape should still allow the cheek to move freely.
- Loupe magnification is helpful for accurate identification of anatomical landmarks, for precise tissue dissection, and for perfect approximation.

Approach

- Successful application of this cleft lip repair is facilitated by highlighting conceptual differences between the rotation-advancement repair and anatomic subunit repair.
- Important landmarks are marked out, never compromised, and incisions are made for closure that follows anatomical subunits.
 - Paradigm shift: Spend more time marking before any incisions are made and the surgeon is committed to the plan.
- Calipers are used to measure incisions for perfect length match.
 - Paradigm shift: The artistic "eye" is supplemented by precise measurements.
- Foundation of repair is in the muscle.
 - Paradigm shift: Extension of skin incision outside of the proposed philtrum to achieve rotation is not required.

- Inferior triangle is placed above the cutaneous roll. This location restores the cutaneous roll without interruption and achieves any additional lip lengthening required for the skin.
- Paradigm shift: Triangle is premeasured. Most measure 1 to 2 mm because the muscle repair and mucosal M flap both contribute to lip lengthening.

TECHNIQUES

■ Planning the Repair: Medial Nasolabial Element

- Markings are made with methylene blue dye after the patient is prepped and draped.
 - Markings of landmarks and anatomic contours are made with dots at the landmarks listed below and along the line of interest for measurement, incision, or alignment of elements.
 - Tattoo all points to prevent loss of landmarks.

Vermilion, Cupid's Bow, and Nose

- Mark the junction of the vermillion and mucosa along both medial and lateral lip elements (**TECH FIG 1A**).
 - This helps determine the vermillion height discrepancy and points of closure and ensures a continuous natural curve is achieved.
- The following marks are placed on the *medial lip element* (**TECH FIG 1B**):
 - Mark the peak of Cupid's bow on the noncleft side with one point above and below the cutaneous roll.
 - Mark the trough of Cupid's bow.
 - Mark the peak of Cupid's bow on the cleft side with one point above and below the cutaneous roll. The point above the cutaneous roll guides the placement of the opening incision for insertion of the triangular cutaneous flap, if required. Choose this point just medial to the actual peak of the Cupid's bow because it is difficult to surgically create a curve. It is preferable to use the existing curve on the lateral lip element.
 - Mark the columellar points: one central and two adjacent that are symmetrically distanced from the center and lie at the superior end of the philtrum.
 - The noncleft side of the medial lip element will guide you to pick the

superior extent of the philtrum, and you can mirror this onto the anticipated created philtrum on the cleft side of the medial lip element (**TECH FIG 1C**).

TECH FIG 1 • Medial lip markings. A. Vermilion. The border between the vermilion and the mucosa is marked. **B.** Cupid's bow. **C.** Nose. (Copyright © David Chong.)

- Remember that the apparent curve of the noncleft side philtral column is due to the unopposed action of the unrepaired orbicularis oris and is almost always a straight line in the Caucasian population once repaired.
- In the noncleft nasal sill, mark the point where the medial footplate of the medial crus meets the nasal floor (Nx). This point is used to guide the nasal sill closure on the cleft side.

Measurements and Interpositional Triangle

- Measure the distance on the *noncleft side* from the superior extent of the philtrum to the peak of Cupid's bow above the cutaneous roll (**TECH FIG 2A**).
- This is the total height of the philtrum (*a*) on the noncleft side that you need to recreate on the cleft side philtrum.
- Measure the distance on the *cleft side* from the superior extent of the philtrum to the peak of Cupid's bow above the cutaneous roll with tissue

unfurled to mimic repair (**TECH FIG 2B**). This is the height of the cleft philtrum (b). It is key to unfurl the convex surface of the medial lip during this measurement; this maneuver aims to mimic the lengthening achieved with muscle dissection and repositioning with mucosal release.

- Perform a simple calculation to decide the need for an opening triangle: subtract the distances between the philtrum of the noncleft side and the cleft side ($a - b - 1$) (**TECH FIG 2C**).
 - Note that 1 mm of length will be achieved by the Rose-Thompson effect (**TECH FIG 2D,E**). If greater than 1 mm of difference remains between the philtral lengths, a cutaneous triangle from the lateral lip element will be required, with its base equal to the distance deficit remaining.
 - Most cutaneous triangles have a base width of 1 mm (70% of cases), 1.5 mm (20% of cases), or no triangle (10%) depending on whether the cleft is complete or incomplete.
- Place a reference point in the nasal sill at the junction of the skin and mucosa on the cleft side of the medial lip. This point (N_m) will guide you to place the alar base at the correct vertical position. Ideally, this point is placed in mirror image to the contralateral side, where the medial footplate of the medial crura meets the nasal floor (N_x). Practically, you would like to maximize the amount of skin available for nasal closure when learning to perform this lip repair. Therefore, this reference point should be placed at the vermilion cutaneous junction. In the initial learning phase of this repair, there is a certain amount of “cut as you go” during closure of the nasal sill, as permitted by the laxity of the skin in this region.
- Tattoo all points listed above to prevent loss of landmarks.

TECH FIG 2 • Medial lip measurements. **A.** Noncleft philtral column length is measured (*a*). **B.** Length of the cleft philtrum is measured while placing gentle downward traction (*b*). **C.** To determine whether an interpositional triangle is needed, the difference between the philtral heights of the cleft and noncleft sides is calculated by subtraction ($a - b - 1 = c$ [height of equilateral triangle]). **D.** Rose-Thompson effect. Original description of lip lengthening with biconcave excision closure by Rose in 1879. **E.** Rose-Thompson effect applied to the anatomic subunit repair.

■ Elevate the Lateral Lip Element

- Before placing the lateral lip markings, release the gingivobuccal sulcus and lateral nose at the level of piriform aperture to facilitate marking the nasal closure in complete clefts. Incise along the gingivobuccal sulcus beginning at the junction point in the nasal floor between the vestibular mucosa, oral mucosa, and nasal skin.
- Continue the incision laterally and superiorly into the nasal cavity (**TECH FIG 3A**).
- Dissect the lateral lip element and alar base off of the maxilla in a supraperiosteal plane (**TECH FIG 3B**).
- Place one digit along the inferior orbital rim to help control the extent of dissection needed and to prevent inadvertent entry into the orbit, as the maxilla is vertically short in this age group.
- Blunt dissection will prevent infraorbital nerve injury.
- Dissect all attachments off the lateral and inferior portions of the piriform aperture to ensure that the aberrant connection between the lower lateral cartilage and the maxilla is released.
- Release is complete once the lateral lip element and alar base are sufficiently mobile to allow tension-free repositioning of the alar base, permitting visualization of the repair and symmetrical nasal closure.

TECH FIG 3 • A. Lateral labial element release. **B.** Supraperiosteal dissection of lateral lip element. The shaded area is undermined in the supraperiosteal plane to allow mobilization and medial advancement

of the muscle.

■ Planning the Repair: Lateral Nasolabial Element

Nordhoff's Point

- With the lateral lip element and alar base mobilized, you may now predictably mark the lateral lip:
- Mark the point of lip closure “Nordhoff’s point” with a point above and below the cutaneous roll³ (**TECH FIG 4**). Parameters used to select this point include the following:
 - Quality and shape of the cutaneous roll
 - The thickest portion of the red lip (vermilion)
 - The most anterior projecting point (need to assess from head of table)
 - The authors do not use the distance from commissure to the peak of Cupid’s bow for determining the point of lip closure. It is unreliable due to the variable extent of contraction that may be present from the orbicularis oris muscle.

Nasal Sill

- Mark the point for the nasal sill closure (Nl).
 - It is helpful to have an assistant to simultaneously assess the symmetric positioning of the alar base in all planes.
 - Looking from the head of the bed, mimic nasal closure by moving the lateral lip element to the medial lip element and position the alar base on the cleft side at the same vertical height as the noncleft side.
 - From the submental view, the assistant should use forceps to elevate the slump of the alar rim and recreate an oval nostril shape with a symmetric diameter.
 - When the correct diameter of the nostril and the correct alar base position are determined compared to the noncleft side, place a point (Nl) on the lateral lip skin to mark closure to the equivalent point on the medial lip (Nm) (**TECH FIG 5**).
 - When these two points meet (Nm and Nl), the nostril should be of equal diameter, and the vertical position of the alar bases should be the same.
- The alar base vertical position (in the cephalad-caudal dimension) is most difficult to correct postoperatively if it is placed too low or too high relative to the noncleft side.

- In practice, you will find that minor adjustments in the width of the nasal floor are achievable so err on the side of placing Nl more medial during the initial application of this repair. This can then be adjusted by excising excess tissue during nasal closure. As you begin to use this repair with increasing confidence, you will trust the point you mark, minimizing the need to cut as you go.

Matching Nasolabial Lengths

- Now, you have two points of closure: one on each side of the lip to match the vermilion and white lip and one on each side of the nasal sill to match and achieve the right vertical height for the alar base and symmetrical diameter of the nostril opening (**TECH FIG 6A**).
- Finally, you must mark the following on the lateral lip:
 - The dimensions of the inferior triangular skin flap
 - The labial and nasal sill incisions within the confines of the two fixed points of Nordhoff and nostril sill closure (**TECH FIG 6B**)
- Set the caliper equal to the distance of the noncleft philtral height (*b*). Orient the caliper to determine the inclination of the line *b* on the lateral lip.
 - Select the ideal orientation to account for the caliper distance (*b*), the inferior triangle size (*t*), and nasal floor distance (*d*) to tailor the “advancement flap” for precise lip and nasal closure (**TECH FIG 6C**).
- Mark the advancement triangle in the vermilion as required by the discrepancy in the vermilion height and volume between the cleft and noncleft sides. The red lip advancement flap includes mucosa.

TECH FIG 4 • Selection of Nordhoff's point. **A.** This point is selected along the vermilion border where the cutaneous roll is thick, just starting to flatten, and beginning to converge with the red line (*arrowhead*). The distances marked by x should be equal at the end of surgery but are not measured when marking as they are hard to determine prior to repair. **B.** When marking Nordhoff's point, it is important to always mark at 90 degrees to the cutaneous roll. With appropriate positioning of Nordhoff's point, closure of the labial elements should result in mirror-image symmetry of the cutaneous roll and red line of Cupid's

bow. **C.** The most anterior projecting point on the lateral lip.

6: ● Medial nasal sill point = Nm
7: ● Lateral nasal sill point = NI

TECH FIG 5 • Selection of nasal sill points of closure.

A. The lateral point of the nasal sill is determined by lifting the cleft ala medially. Use the noncleft side nasal sill point (Nx) to help select the cleft side nasal sill points of closure (Nm and NI). **B.** Alar bases are leveled.

2: ● Peak of Cupid's bow—
vermilion edge of cutaneous roll
3: ● Peak of Cupid's bow—
skin edge of cutaneous roll

5: ● Lateral columella
6: ● Medial nasal sill point (Nm)
7: ● Lateral nasal sill point (NI)

TECH FIG 6 • Lateral lip markings. Lip (**A**) and nasal (**B**) points of closure are marked, and then limbs are

drawn between those points (**C**). Like an articulated ruler, with the two end points fixed, the two intermediate points are selected by establishing best fit with known measurements. (Copyright © David Chong.)

- By planning the repair, one recognizes the variability of unilateral cleft lip presentations and individualizes the repair to the presenting deformity, much like a tailor would measure a suit for an individual. With this approach, you will achieve a balanced lip with:
 - The correct thickness of vermilion and mucosa of the red lip
 - A continuous cutaneous roll
 - A symmetric Cupid's bow
 - A length-matched closure of the lip incision that reflects the philtral column position
 - A nasal sill closure with the appropriate orientation, position, and diameter to match the contralateral naris
-

■ Dissection

Medial Labial Element

- Incise the medial lip element first (**TECH FIG 7**). This allows you to verify that prior to cutting the lateral lip element, you are able to achieve the necessary rotation to create a vertically balanced lip and ensure no adjustments are required to the size of the triangle.
- Use a no. 11 blade to incise along the medial lip markings. It is critical to precisely cut perpendicular to the cutaneous roll. If a triangle is planned, make the opening incision above the cutaneous roll as your final cut to level Cupid's bow and ensure its size is appropriate.
- Incise along the markings of the vermilion and continue the incision onto the mucosa and release the maxillary frenulum.
- Release the aberrant muscular insertions to the anterior nasal spine. Perform minimal dissection of the muscle from the skin and mucosa.
- Elevate the skin along the vermilion-cutaneous junction (analogous to C-Flap elevation) to facilitate nasal sill closure and allow access to the nasal

septum.

- Elevate the mucosa (analogous to M-flap elevation) off the medial cleft edge to inset at the site of the maxillary frenulum release and elongate the medial lip mucosa.

Nasal Structures

- Expose the caudal septum on the noncleft side with elevation of the mucoperiosteal flaps for direct visualization of the cartilage. Reposition the caudal septum with gentle traction toward the cleft side.
- The amount of lower lateral cartilage dissection varies according to surgical preference.⁴⁻⁷
- If nasal degloving is to be performed, place scissors carefully in the plane between the skin and medial crura. Gently dissect in this plane between the skin and the cartilage from the medial crus toward the lateral crus.

TECH FIG 7 • Medial labial incisions and dissection of the skin, muscle, and mucosa.

- Opponents of nasal cartilage degloving consider the risk of cartilage injury, tissue destruction, subsequent scarring, and impaired growth to far

outweigh the minimal benefit achieved with this degloving. In primary nasal correction without cartilage degloving, the correction is achieved with release of abnormal ligamentous attachments at the piriform and suture techniques, avoiding the risks listed above.

- The muscle release, repositioning, and approximation are the foundation of the lip repair.
- Verify the muscle is sufficiently released by measuring the lip length. Once committed to the opening incision, make the cut perpendicular to the philtral incision and above the cutaneous roll with a beaver blade.
- By incising and committing to the medial lip plan first, you can then adjust the lateral lip markings if the planned triangle size was incorrect. This is particularly helpful in the learning stages of this technique (the planned triangle may not be necessary or the wrong size).

Lateral Nasolabial Element

- Use a no. 11 blade to incise the lateral lip and a beaver blade to make the fine incisions around the triangle.
- Release the muscle from the alar base. Continue dissection laterally for a 2-cm distance dividing the muscle to allow for its advancement and to create a muscle of symmetric height for repair.
- Perform dissection between skin and muscle, especially along the superior portion of the lateral lip to allow for advancement. Perform minimal release of the muscle from the underlying mucosa.
- Elevate the nasal floor off the nasal vestibule to allow for repositioning in a horizontal plane for nasal floor closure.
- If cartilage degloving is being performed for primary nasal correction, complete the degloving in the plane between the skin and cartilage joining the previously dissected pocket.

■ Closure of the Lip

Muscle Repair

- The muscle repair sets the foundation for the lip repair. To correctly position the muscle elements for repair, have an assistant use a skin hook to lengthen the medial lip element to balance the Cupid's bow (taking care not to excessively elongate) and another skin hook to hold the lateral lip element at

the ideal position for a lip closure (**TECH FIG 8A**).

TECH FIG 8 • A. Level Cupid's bow to position the muscle elements for repair. **B.** A. In repair of a cleft lip, it is essential to release the aberrant orbicularis oris muscle insertions and reposition the muscle fibers to restore continuity. After release, repositioning, and repair of the orbicularis oris muscle, a superior gathering suture is placed (**C, right**) to improve the shape of the lip on profile view (**D**).

- With the setup outlined above, repair the muscle beginning superiorly. Place the initial stitch superiorly to set the lip length and set the alar base in a symmetrical vertical position. To ensure the cutaneous roll points of closure

are perfectly matched, check the alignment of the points of closure after each successive muscle stitch.

- After repairing the length of the muscle, consider placing a plication suture at the superior end of the muscle repair at the base of the columella. This accentuates the pout of the repaired lip (**TECH FIG 8B–D**).
- Repair the mucosal incision with eversion of the mucosal edges. Ensure correct approximation of the mucosal lengths and excise excess length at the cephalad margin as required.

Cutaneous Approximation

- Suture the labial skin and the vermilion without any cutaneous excision or alteration of the labial incisions. A perfectly approximated closure of the labial elements should be achieved based on the planned markings.
- The only “cut as you go” occurs at the nasal sill where some adaptation is often required to ensure the right diameter and shape of the nostril opening.

■ Primary Nasal Correction: Suture Techniques

- Suture techniques detailed below necessitate that the alar base and aberrant nasal attachments to the piriform and underling maxilla are completely released.
 - The alar bases must be symmetrically repositioned and the caudal septum must be centralized.
- If cartilage degloving was performed:
 - Place an alar shaping suture as an interdomal suture between the genua of the lower lateral cartilages (LLC).
 - Place a lower lateral hitching suture with an absorbable suture to secure the dome of the LLC to the contralateral nasal bone periosteum. This elevates the slumped LLC. Beginning from inside the nasal vestibule on the cleft side, pierce the suture through the nasal mucosa, capture the dome of the slumped LLC, exit the nasal skin with grasped nasal bone periosteum, and back through the same cutaneous needle puncture to return to the nasal vestibule through the same tissues.
- If cartilage degloving was not performed:
 - Place an internal nasal valve plication suture in the vestibule between the upper and LLC to recreate the scroll area.
 - Place an alar transfixion suture to lateralize the vestibular web. Beginning

from inside the vestibule, pierce through the nasal mucosa just below the caudal LLC and exit the skin at the alar-facial junction. Re-enter the same cutaneous puncture hole but exit more posteriorly in the nasal mucosa. Tying the knot will lateralize the nasal mucosa.

PEARLS AND PITFALLS

Planning

- Important landmarks are marked and never compromised.
- There should be no “cut as you go” on the lip. The labial closure should be precisely measured and tailored fitted because compromise in the lip closure point is unforgiving.
- Spend more time marking before any incisions are made and commit to a plan.
- It may be disconcerting initially as a lot more tissue seems to be discarded than when “hedging your bets” by unnecessary preservation of tissue.

Markings

- Choose the cleft side of Cupid’s bow point just medial to the actual peak of the Cupids bow as it is difficult to surgically create a curve. Pick a slightly more lateral point on the lateral lip element (which has the curve).
- The triangular cutaneous flap is smaller than anticipated for two main reasons:
- The skin is elastic and rests in a concave contour due to the aberrant insertion of the muscle. It will lengthen with release of the muscle and dissection between these layers.
- Rotation of the medial lip is also achieved by the muscle repair and the mucosal release.

Measurements

- Use calipers for measurements. This results in length-matched incisions and precise alignment.

Muscle repair

- The muscle is detached from its abnormal insertion, and the lateral lip muscle is advanced into the gap superiorly as the muscle released medially is drawn caudally to achieve lip length. This allows planning the skin incision to mimic the philtral column position rather than the misguided intention that it achieves rotation.

Inferior triangle above the cutaneous

- Creates a continuous cutaneous roll without interruption. Insert any required triangle in the shadow of the roll, that is, just above

roll

the roll.

- Achieves any additional lip lengthening required.
- Work out the precise size of triangle and confirm measurement by cutting medial lip element first.

FIG 1 • Preoperative and postoperative images of an infant with cleft lip and palate following repair with anatomical subunit technique. (Copyright © David Chong.)

POSTOPERATIVE CARE

- Prevent crusting along the suture line with incision care.
- Apply saline as required to prevent scab and then emollient.
- Sutures are removed after 5 days.
- Nasal stents are kept for up to 6 weeks.

OUTCOMES

- Since 2008, Dr. Chong has performed 200 consecutive cleft lip repairs using the technique described (**FIG 1**).
- Nasolabial revisions were required in three cases (1.5%), one for alar repositioning and two for retained permanent suture.
- There have been no revisions required for a shortened lip.

COMPLICATIONS

- Infection
- Hemorrhage

- Lip or nasal revision required for asymmetry
- Poor scarring
- Nasal airway obstruction

2 Unilateral Cleft Lip Repair: Millard/Mohler Modifications

CHAPTER

Roberto L. Flores and Gerald J. Cho

DEFINITION

- A unilateral cleft lip is a congenital separation of the upper lip. The degree of clefting can be microform, minor form, incomplete, or complete.
 - Microform
 - Discontinuity of the vermilion-cutaneous junction
 - Cupid's bow symmetrical
 - Slight notching of mucosal free border
 - Variable nostril deformity and alveolar defect
 - Minor form
 - Vermilion notch greater than 3 mm above the level of Cupid's bow on the noncleft side
 - Discontinuity of orbicularis oris
 - Nasal deformity
 - Alveolar cleft present
 - Incomplete
 - Complete full-thickness separation of upper lip with intact nasal sill or a Simonart band along the nasal floor
 - Complete
 - Complete full-thickness separation of upper lip

ANATOMY

- Both the soft (upper lip and nose) and hard tissues (maxilla, septum, lower lateral cartilages of nose) are affected (**FIG 1**).
- Upper lip—The deformities in this area can be categorized into those affecting

the medial and lateral lip elements.

- In the medial lip element, Cupid's bow is preserved but with vertical deficiency of the vermillion. The columella and philtral column are shortened on the cleft side. The orbicularis oris has an abnormal and unilateral insertion at the nasal base, and its disruption results in vertical shortening of the medial upper lip, superior rotation of the Cupids bow, and vertical shortening of the vermillion.
- In the lateral lip element, the height and transverse length are shortened. Medially, there is a distinct point where the white cutaneous roll and junction of the wet and dry vermillion start to converge medially (Nordhoff point). The pars superficialis on the lateral lip alters the direction of this muscle to run almost vertically in the area below the ala, leading to aberrant attachments to the nostril and periosteum of the piriform aperture. This leads to a vertically foreshortened lateral lip, sometimes producing a bulge in this area.
- Nose—The alar base on the cleft side sits on the piriform margin of the maxilla, which is laterally and posteriorly displaced. The malposition of the bony foundation combined with separation of the orbicularis oris causes unopposed action of the ipsilateral zygomaticus major. This results in widening of the nostril, depression of the alar dome, and canting of the columella toward the cleft side (see **FIG 1**). Unilateral attachment of the orbicularis oris to the medial crura footplates, anterior nasal spine, and caudal septum on the noncleft side exacerbates the columellar tilt and contributes to deviation of the caudal septum toward the noncleft side. Internally, the caudal portion of the ala has a vestibular web. The underlying cartilaginous structures are also malformed. On the cleft side, the medial crus of the lower lateral cartilages is shortened, and the lateral crus is elongated and inferiorly displaced. The septum is dislocated out of the vomer and bows toward the cleft side.
- Maxilla—The underlying skeleton forms the platform upon which the soft tissues rest. Thus, the skeletal abnormalities of the maxilla can explain many of the soft tissue abnormalities seen, particularly in the nose. The greater segment of the alveolus is anteriorly rotated due to the fetal protrusion of the tongue. The lesser segment of the alveolus rotates posteriorly. The medial buttress of the maxilla can be hypoplastic and posteriorly displaced.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The preoperative assessment of a patient with a unilateral cleft lip includes

complete physical exam with assessment for other comorbidities. Facial exam includes the side (left vs right vs midline), the degree of clefting (microform, minor form, incomplete, or complete), and the extent of nasal deformity.

IMAGING

- Typically not needed unless within the context of a midline or facial cleft

SURGICAL MANAGEMENT

- This surgery is often the first step in the larger multidisciplinary treatment plan for cleft care.
- The quality of the primary repair establishes the initial function and appearance for the patient and has great bearing on their future quality of life.
- Nasoalveolar molding (NAM) is strongly recommended for patients with a complete cleft or a significant nasal deformity.
- Microform clefts can be repaired with less extensive methods than a full rotation advancement.
- Minor forms can be repaired with a modified rotation-advancement-type repair with complete primary nasal reconstruction.
- Incomplete and complete clefts can be repaired with a full rotation-advancement-type repair.
- Initial lip and nose repairs are performed at approximately 3 months of age.

FIG 1 • The soft (upper lip and nose) and hard tissue (maxilla, septum, lower lateral cartilages of nose) anatomy of a left complete unilateral cleft lip.

Preoperative Planning

- The authors use NAM in patients with a complete cleft or a significant nasal deformity. As mentioned above, a cleft through the maxilla not only disrupts the platform upon which the soft tissues sit but also interrupts the dental arch. NAM can help correct the outwardly rotated greater segment and posterolaterally displaced lesser segment. The correction of the skeletal platform into an anatomic position helps place the lip and nose into a more favorable alignment. Furthermore, when the alveolar segments are aligned within 1 mm, a gingivoperiosteoplasty can be performed, which can avoid a secondary bone grafting procedure in 60% to 73% of patients without detriment to midface growth by midterm follow-up. For these reasons, we feel that NAM provides a more predictable lip and nose repair and potentially decreases the overall number of surgical procedures for the child.
- NAM typically commences 2 weeks after birth and is completed after 10 weeks of therapy in patients with a unilateral cleft.

Positioning

- Supine with gentle neck extension from a shoulder roll

Approach

- There are many techniques to repair a unilateral cleft lip, each with its own advantages and disadvantages. In this chapter, we will present Cutting's modification of the extended Mohler repair.
- In this approach, there are eight main steps to the operation: markings, incisions, medial lip dissection, lateral lip dissection, mucosa closure, nasal dissection, lip closure, and nasal refinement.

TECHNIQUES

■ Millard/Mohler Modifications for Unilateral Cleft

Lip Repair

Markings (**TECH FIG 1A–D**)

- Medial and lateral lip elements (**TECH FIG 1A**)
 - Medial lip element: The depth (point 1) and height of the noncleft side (point 2) are identified and marked. The distance between these two points is used to mark the height of the Cupid's bow on the cleft side (point 3). The white roll usually starts to disappear at this point. If Cupid's bow is wide or indistinct, the marks can be placed more narrowly so that less downward rotation is required.
 - Lateral lip element:
 - The height of the lip from the alar base to the height of the Cupid's bow on the noncleft side is measured with a caliper, and the vertical distance is used to locate the corresponding white roll point on the lateral lip element (point 4). Some surgeons use the widest point of the vermilion (Nordhoff point) to determine point 4. However, in patients with a wide cleft, Nordhoff point will commonly result in a vertically foreshortened lip. Using the vertical height of the contralateral upper lip can sacrifice horizontal lip length for preservation of vertical lip height. The horizontal lip discrepancy will correct over time; however, a vertically shortened upper lip will remain.
- Mohler Back Cut (**TECH FIG 1B**)
 - The apex of the back cut is critical to the success of the design (see Pearls below). This point (point 5) is placed approximately 1.5 mm superior to the base of the columella and just over halfway (four-sevenths) across the noncleft side.
 - A line is drawn connecting point 5 to a point just lateral to point 3. This line should be bowed out to the same degree as the philtral column of the unaffected side to recreate the subtle curve.
 - A straight line is drawn from the apex of the Mohler backcut (point 5) to the height of the philtrum on the noncleft side but no farther (point 6). The angle formed by these two lines and length of the backcut will affect the degree of downward rotation of the Cupid's bow.
- C flap and M flap on the medial lip element (**TECH FIG 1C**)
 - C flap: A line is drawn along the skin/mucosa junction lateral to point 3. Care is taken to incorporate as much white lip into the C flap as possible while avoiding the mucosa (see Pearls below).

- M flap: The medial/inferior border of the M flap is drawn as a straight line starting from point 3 and perpendicular to the white roll. A second line is drawn on the vermillion of the medial lip element as an oblique line starting at a point 1 mm inferior to the white roll, traveling laterally and inferiorly to the red line. This is the receiving incision for the Nordhoff triangular flap.
- Alar base and L flap on the lateral lip element (**TECH FIG 1D**)

A

B

C

TECH FIG 1 • Markings. **A.** Key tattoo points. **B.** Mohler back cut. **C.** C flap and M flap. Dashed blue line represents the receiving incision for a vermilion triangular flap if used. The dashed red line represents the intranasal incisions on the septum and vomer made during nasal floor closure. **D.** Alar base and L flap (L) outlined in *blue*. The *dashed blue line* is the triangular flap as described by Nordhoff. *Dashed green line* is the intranasal incision at the piriform aperture, and the *dashed red line* is the gingivobuccal sulcus incision, which will be made at the time of the lateral lip dissection.

- Alar base: A small incision is marked along the alar crease on the cleft side with care not to extend this incision around the alar base.
- L flap: The border of the L flap is then marked by first marking an incision 1.0 mm inferior to the white roll on the lateral lip element. This mark then transects the white roll perpendicularly and then curves swiftly and softly to meet the medial edge of the previously made mark on the alar crease. The remainder of the L flap can then be made with or without the addition of a vermilion triangular flap, as described by Nordhoff. When marking the L flap, care is taken to extend the mark just superior to the alveolus. This

will base the L flap off of the lateral nasal wall and not the alveolus, as originally described by Millard.

- Points 1 to 6 are tattooed. The lip and nose are infiltrated with 0.5% lidocaine with 1:200 000 epinephrine.

Incisions

- All premarked incisions are made through skin and mucosa.

Medial Lip Dissection (**TECH FIG 2A,B**)

- M flap is elevated in a submucosal plane (**TECH FIG 2A**).
- C flap is elevated in the subcutaneous plane with care to preserve the underlying orbicularis oris (see **TECH FIG 2A**).
- Mohler back cut (**TECH FIG 2B**).
 - A transverse incision is made across the full-thickness orbicularis oris muscle where it abnormally inserts at the nasal base. This incision is made at the base, not the apex, of the Mohler back cut. If this incision is made at the apex of the back cut, the medial crura will be transected. Care should also be taken to avoid going through the underlying mucosa during this incision.
 - Complete full-thickness transection of the muscle should be confirmed by placing a small single hook into the medial lip element and pulling the lip down. The lip should rotate downward with no tension.
 - If additional downward rotation is still required, the labial frenulum is horizontally transected. This defect may be filled by the mucosa of the lateral lip element.
- Medial lip element preparation: The philtral skin is dissected free from the muscle in a subcutaneous plane up to but not past the philtral dimple.

Lateral Lip Dissection (**TECH FIG 3**)

- L flap elevation:
 - The L flap is carefully elevated from the orbicularis oris in the subcutaneous and submucosal plane. As one approaches the area of the piriform aperture, the dissection plane changes from a submucosal to a subperiosteal plane.
 - A Woodson elevator is then used to create a subperiosteal pocket in the interior/lateral aspect of the piriform aperture. A horizontal incision is made at the exact border of the lateral nasal wall with the nasal floor. An incision

is made at the base of the vomer, and a vomer flap is elevated with the periosteal elevator. The lateral nasal wall flap and vomer flap will be used to close the anterior nasal floor later in the surgery.

■ Piriform aperture incision:

- A vertical intranasal incision is made at the border of the nasal mucosa and squamous skin to meet the superior border of the L-Flap. Sharp dissection is performed to reach the bone of the piriform aperture.
- Subperiosteal dissection will complete the elevation of the L flap posteriorly until it is based off the lateral nasal wall.

TECH FIG 2 • Medial lip dissection. **A.** M flap (m) elevated in a submucosal plane and turned down. C flap elevated in the subcutaneous plane. **B.** Mohler back cut. *Dashed yellow line* represents a transverse incision made across the full-thickness orbicularis oris muscle where it abnormally inserts at the nasal base. Complete full-thickness transection of the muscle should be checked by placing a small single hook into the medial lip element and pulling the lip down. The lip should rotate downward with no tension. The philtral skin is dissected free from the muscle in a subcutaneous plane up to but not past the philtral dimple.

TECH FIG 3 • Lateral lip dissection. L flap (L) elevated in a submucosal plane and shown retracted medially. The stippled area represents the L flap that will be trimmed before inset into the lateral nasal wall. As one approaches the area of the piriform aperture (*dashed green line*), the dissection plane changes from a submucosal to a subperiosteal plane. A gingivobuccal sulcus incision (*dashed red line*) is made in continuity with the piriform aperture incision, with care to preserve the L flap. A suprapariosteal dissection is made across the maxilla to fully mobilize the alar base and lateral lip element. The alar base skin (a) should

be elevated as a thick split-thickness skin graft so that a layer of dermis is present on the underlying dermal-muscular pennant flap.

■ Gingivobuccal sulcus incision:

- A gingivobuccal sulcus incision is made in continuity with the piriform aperture incision, with care to preserve the L flap. A supraperiosteal dissection is made across the maxilla to fully mobilize the alar base and lateral lip element. In cases where presurgical orthopedics is not used, this dissection may continue widely across the face in the maxilla.
- Tension-free translation of the alar base flap to the anterior nasal spine will demonstrate adequate dissection.

■ Alar base flap:

- The alar base skin should be elevated in a thick split-thickness skin graft plane so that a layer of dermis is present on the underlying muscular flap. The dermal-muscular pennant will be used to relocate the alar base.

■ Lateral lip element preparation:

- The lateral lip skin is mobilized from the orbicular oris as far lateral as the alar base incision.

Mucosa closure: If gingivoperiosteoplasty is to be performed, it should be completed before the mucosa is closed.

■ L flap inset (**TECH FIG 4A**)

- The L flap is sutured under tension to the base of the piriform aperture incision. Excess L flap is trimmed, and the remainder of the L flap is sutured into the defect created by the piriform aperture incision.

■ Nasal floor closure (**TECH FIG 4B**)

- The lateral nasal wall flap/L flap is sutured to the vomer flap using several absorbable sutures. The sutures are placed first in a simple fashion and then in a horizontal mattress fashion to create a watertight closure of the nasal floor. Closing the anterior nasal floor will facilitate successful gingivoperiosteoplasty and/or alveolar bone graft.

■ Oral mucosa (**TECH FIG 4C**):

- The gingivobuccal sulcus incision is closed using several oblique oriented sutures. This will relieve tension from the midline of the mucosal reconstruction. The mucosa of the upper lip is then closed with simple

sutures, with care not to incorporate muscle in the mucosal reconstruction.

Nasal Dissection (**TECH FIG 5**)

- The rhinoplasty portion of this procedure will elongate the columella and elevate the depressed lower lateral cartilage.
- A hemimembranous septum incision is first made on the cleft side.
- Through the apex of the Mohler backcut, blunt dissection is performed to create a dissection pocket between the medial crura. This dissection pocket is then connected with the hemimembranous incision in the septum, and this dissection is continued superiorly toward the septal angle.
- Dissection scissors are then inserted through this pocket and over the upper and lower lateral cartilages on the cleft and noncleft side.
- Careful blunt dissection will create a subcutaneous pocket over the upper and lower lateral cartilages in preparation for rhinoplasty. Care is taken not to close the dissection scissors in the dissection pocket, as it can lead to damage to the lower lateral cartilages.

A

B

TECH FIG 4 • Closure. **A.** Excess L flap (*L*) is trimmed, and the remainder of the L flap is sutured into the defect created by the piriform aperture incision (*A* to *A'*, *B* to *B'*, *C* to *C'*). **B.** The L flap is then sutured to the vomer flap (*V*) to close the nasal floor. **C.** The gingivobuccal sulcus incision is closed using several oblique oriented sutures (*blue arrows*); this will relieve tension from the midline of the mucosal reconstruction (*green arrow*). The mucosa of the upper lip is then closed with simple sutures, with care not to incorporate the musculature in the mucosal reconstruction.

- If no NAM is performed, an additional nostril rim incision is made and a dissection pocket created to connect the rim incision to the subcutaneous pocket underneath the nasal tip.
- A retractor is used to elevate the depressed lower lateral cartilage in a supercorrected position.

TECH FIG 5 • Nasal dissection. Blunt-tipped scissors are inserted through the apex of the Mohler back cut and at the intranasal incision made at the septal angle. Blunt dissection frees the underlying lower lateral cartilages.

- A long-lasting absorbable suture is then placed as a horizontal mattress to affix the medial crus on the cleft side in its newly elevated position. Several such sutures are placed from superior to inferior to affix the medial crus in its superior location and help shape the columella.
- An additional row of horizontal mattress sutures is then placed using transfixion sutures to affix the medial crura to the cartilaginous septum. Elongation of the columella should be appreciable at the end of this point of the procedure.
- If a nostril rim incision is used, a suture is placed from the cleft side lower

lateral cartilage to the upper lateral cartilage to further reinforce the elevated position of the lower lateral cartilage.

Lip Closure (**TECH FIG 6A,B**)

- Repositioning of alar base (**TECH FIG 6A**)
 - A long-lasting absorbable suture is first placed through the dermomuscular pennant underneath the alar base. Using this suture as a leash, the location of the caudal septum is sighted and then placed through this area and the medial crus on the noncleft side. Tying the suture down will set the alar base in an anatomic position, medialize the columella, and straighten the anterior septum.
 - A second such suture is placed to reinforce the first.
- Muscle (see **TECH FIG 6A**)
 - The orbicularis oris is then reconstructed from superior to inferior using several buried sutures. Prior to reconstruction, excess orbicularis oris is carefully trimmed so that the skin edges are perfectly opposing at the completion of the muscular reconstruction. The superior suture may be attached to the anterior nasal spine to prevent elongation at the upper lip.

TECH FIG 6 • Closure. **A.** The dermal-muscular flap at the alar base is sutured to the area of the anterior nasal spine and the medial crus on the noncleft side (*dashed light blue arrow*). The orbicularis oris is then reconstructed from superior to inferior. **B.** The white roll point is first reconstructed, and the remainder of the upper lip is meticulously closed using several fine permanent sutures. The vermilion is also inset at this time. If a triangular flap is used, this is trimmed and

inset.

- Upper lip skin (**TECH FIG 6B**)

- The white roll point is first reconstructed, and the remainder of the upper lip is meticulously closed using several fine permanent sutures. The vermilion is also inset at this time. If a triangular flap is used, this is trimmed and inset.

- C-Flap inset (see **TECH FIG 6B**)

- In the extended Mohler repair, the C flap is used to fill the defect created by the downward rotation of the Cupid's bow. The C flap is carefully scored and cut. The C flap is then inset into this defect, and the columellar incision is also closed with several simple sutures. The alar base incision is also closed at this time. Excess C flap and alar skin are also trimmed, and the nostril floor is closed.

- Nostril floor (see **TECH FIG 6B**)

- Care is taken to close the nostril floor and the philtral incision in a stair-step fashion to avoid a confluence of four corners at the nostril floor incision.

Nasal Refinement

- Nostril apex elevation (**TECH FIG 7**)

- If NAM was used, the nostril apex overhang is addressed using a long-lasting absorbable suture that is placed just behind the nostril rim, through the depressed lower lateral cartilage on the cleft side, underneath the skin of the nasal tip, and out the nostril on the opposite side. The trajectory of this suture is oblique, directed laterally and posteriorly. The suture is then returned 2 mm behind the exit suture hole in the noncleft side, parallel to the first suture, and returning to the cleft side nostril. Tying down this suture corrects nostril apex overhang and adds to tip definition.

TECH FIG 7 • Nostril apex elevation (*red*) and vestibular web obliterating sutures (*blue*).

- In patients who did not undergo NAM, the depressed lower lateral cartilage is elevated by the previously placed suture from the lower lateral to upper lateral cartilage. A small rim of overhanging skin at the nostril apex is carefully trimmed and the rim incision is closed.
- Regardless of technique, there should be an overcorrection of the depressed lower lateral cartilage such that the cleft side is higher than the noncleft side.
- Vestibular web obliterating suture (**TECH FIG 7**)
 - The vestibular web can be addressed by placing a long-lasting absorbable suture behind the web out of the nasal facial groove; the suture can then be returned through the same cutaneous hole and back into the nostril anterior to the vestibular web. Tying this suture down will obliterate the vestibular web and accentuate the nasal facial groove. Multiple sutures may be required to achieve the full effect.

PEARLS AND PITFALLS

Anatomy	■ It is critical that the surgeon has a thorough understanding and ability to identify the pathologic soft and hard tissue deformities and individualize the surgery as needed.
The apex of the extended Mohler back cut	■ It should be high enough onto the columella to allow for full downward rotation of the Cupid's bow. If point 5 is too low, it will result in inadequate downward rotation. ■ If point 5 is too close to the cleft side, the C flap will be too narrow and inadequately fill the defect created by the downward rotation of the Cupid's bow. ■ Placing point 5 too far toward, the noncleft side will result in a narrow philtral column at the superior aspect of the upper lip.
C flap	■ In wide clefts where presurgical orthopedics (NAM) was not used, it is important to incorporate as much white lip into the C flap as possible because the C flap may be used in its entirety to fill the defect created by the downward rotation of the Cupid's bow. ■ Care must be taken to avoid incorporating mucosa, which will result in the transposition of mucosal tissue onto the nose and upper lip.
Tension-free closure essential for optimal wound healing	■ Medial lip element: Adequate release of the orbicularis oris muscle where it abnormally inserts at the nasal base to allow for full rotation downward ■ Lateral lip element: Supraperiosteal dissection is made across the maxilla to fully mobilize the alar base and lateral lip element. ■ Adequate release of abnormal attachment of cleft-side lower lateral cartilage from piriform rim
Multidisciplinary care	■ Essential for optimal outcomes

POSTOPERATIVE CARE

- Children are placed in elbow restraints for 5 to 7 days.
- A syringe feeder or cleft feeding nipple (ie, Haberman nipple) is used for feeding.
- Sutures are removed after 5 days and the lip taped in compression for 5 weeks.

OUTCOMES

- In experienced hands, primary cleft lip and nasal repair can achieve lasting symmetry to the lip and nose while camouflaging scars within the subunit

borders of the face.

COMPLICATIONS

- Relapse of the nasal deformity
- Scar contracture/widening
- Inadequate multidisciplinary care and follow-up during growth
- Maxillary growth inhibition

3 Salyer Unilateral Cleft Lip/Nose Repair

CHAPTER

Kenneth E. Salyer

DEFINITION

- Cleft lip/nose deformity occurs during embryonic development when there is lack of normal migration and proliferation of neural crest cells leading to failure of the facial prominences to fuse.

ANATOMY

Normal Upper Lip Anatomy

- The foundation of the face is the facial skeleton. The upper lip is supported by the underlying maxillary and mandibular framework, with its teeth and alveolar bone. Alveolar bone develops and matures with primary and secondary tooth eruption.
- The orbicularis oris muscle consists of two well-defined and functional components: the pars superficialis and the deep pars marginalis.
- The pars superficialis is located under the skin of the lip and is related to other facial muscles of expression (levator labii superioris, alaeque nasi, and zygomaticus minor), and these retract the upper lip as a group. The pars superficialis consists of an upper and lower bundle.
 - The upper bundle represents the common insertion of the muscles of facial expression and itself inserts onto the anterior nasal spine, septopremaxillary ligament, and the nostril sill, passing deep to the alar base.
 - The lower bundle derives its fibers from the depressor anguli oris muscle on each side and decussates in the midline, inserting in the skin and forming the philtral ridges of the contralateral side.
- The deep portion of the pars marginalis muscle is responsible for sphincteric

action of the mouth and runs under the vermilion from one modiolus to the other.

- The two portions of the orbicularis oris muscle thus correspond to the double function of the upper lip. The deep pars marginalis, extending from one modiolus to the other, seals the extrinsic facial muscles to open the mouth as a retractor.
- Contraction of the deep pars marginalis, when the mouth is pursed, thickens the vermilion and lengthens the upper lip height. Simultaneous relaxation of the pars superficialis produces perioral fine wrinkles and accentuates the philtral columns while flattening the nasolabial folds.
- In contrast, when the mouth is opened, the contraction of the pars superficialis leads to flattening of the perioral wrinkles and philtral columns and accentuates the nasolabial fold. In addition, the upper lip height shortens. Simultaneous relaxation of the deep pars marginalis decreases the thickness of the vermilion.

Abnormal Cleft Lip/Nose Anatomy (FIG 1)

- Varying degrees of cleft dysmorphogenesis of the lip, alveolus, and palate result in skin, soft tissue, muscle, and skeletal deficiencies with functional and aesthetic imbalance.

FIG 1 • Three-month-old with left unilateral complete cleft lip/nose and palate.

- This affects nasal symmetry in both complete and incomplete unilateral cleft lip/nose deformity by distorting the position of the ala base and shape of the nostril.
- With an interruption of the orbicularis oris muscle in the unilateral cleft lip/nose, the other attached facial muscles pull the ala base more laterally compared to the noncleft side. The existing muscle imbalance also changes the position of the alar cartilage, as well as the orientation of the nostril from an oblique to a horizontal orientation.
- When the muscle inserted on the base of the septum and columella is contracted on the noncleft side, the septum and columella is pulled toward that side. Thus, the severity of the cleft nasal deformity depends on the degree of separation of the orbicularis.
- Hypoplasia of the lesser segment, or base, of the cleft nose results in the displacement of the lower lateral cartilage laterally and inferiorly on the cleft side. The nasal dome is flattened and slumped in a downward position.

- The alar cartilage on the cleft side is flat, giving it the false appearance of having greater length when compared to the contralateral alar cartilage, which also is abnormally displaced to the noncleft side.
- The relationship of the lower lateral cartilage to the septum is normal; however, the septum itself is deformed, thereby tilting the base of the nose toward the noncleft side and the tip of the nose toward the cleft side.
- The following summarizes a list of characteristics typical of a unilateral cleft lip/nose deformity. The degree and severity of the deformities vary, and not all of them are present in each patient.
 - The columella is shorter on the cleft side with its footplate displaced and tethered inferiorly.
 - The base of columella is deviated to the noncleft side.
 - The medial crus of the alar cartilage is shorter on the cleft side.
 - The lateral crus of the alar cartilage on the cleft side is longer and, together with the adherent skin, is drawn to an S-shaped fold.
 - The alar cartilage on the cleft side is displaced in the backward and downward planes.
 - The nasal tip is displaced and asymmetric, with loss of the defining point on the cleft side.
 - The dome on the cleft side is obtuse.
 - The flattened ala results in horizontal orientation of the nostril on the cleft side, and it is usually larger than the opposite side.
 - The entire nostril is repositioned.
 - The base of the ala is displaced posterior and inferiorly where it is tethered to the displaced underlying bone on the cleft side.
 - The nasal floor is lower or absent on the cleft side.
 - The caudal septum and anterior nasal spine are deflected to the noncleft vestibule (**FIG 2**).
 - Septal deviation of varying degrees leads to posterior nasal obstruction on the cleft side due to the deviation of the septum and, often, the narrowing of the internal nasal valve.
 - The lower turbinate on the cleft side is hypertrophic.
 - Nasolabial fistula may be present.
 - The lesser maxillary segment is hypoplastic and displaced on the cleft side.
 - The nasal pyramid is asymmetric.

PATHOGENESIS

- Three major factors influence the nasal deformity in both complete and incomplete unilateral clefts:
 - Muscle imbalance
 - Tissue hypoplasia
 - Asymmetry of the skeletal base

NATURAL HISTORY

- Orofacial clefting is the most common craniofacial birth defect, occurring in 1:500 to 1:750 live births worldwide.
- The incidence of cleft lip in combination with cleft palate is estimated at 1:1000 with a gender ratio of 2:1 (male to female) with reverse gender ratio for cleft palate only.
- In the population of children with cleft lip and/or cleft palate (CL +/- P), approximately 50% have CLP, 30% to 35% CP, and 15% to 20% CL.
- Approximately 15% of CLP patients will have a syndrome, whereas 40% of CP patients are part of a syndrome.

FIG 2 • Anterior nasal spine deviated to the right and noncleft side.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The diagnosis of a cleft lip and/or palate is made by prenatal ultrasonography or by physical examination at birth and in early infancy. A detailed assessment is made of the child's breathing, feeding, growth, and development.
- Airway assessment must exclude the presence of sleep apnea and micro-/retrognathia.
- Assessment of growth and weight is key to identify and monitor feeding difficulty, gastroesophageal reflux, and use of feeding aids (Haberman/Pigeon teat).
- Hearing and middle ear function must be assessed and treated early by an otolaryngologist when associated with cleft palate.
- The plastic surgeon should define in detail the cleft lip type according to the anatomic structures involved, ie, complete or incomplete, unilateral with or without a Simonart band or bilateral, and presence or absence of a cleft palate.
- The child should also be assessed for associated anomalies suggestive of a syndrome, including craniofacial dysmorphism, airway compromise, cardiac defects, ocular and auricular abnormalities, and musculoskeletal anomalies. A genetics referral is suggested if syndromic cleft palate is suspected.

IMAGING

- At 16 weeks gestational age or older, 3D, 4D, and HD in utero ultrasound provide early diagnosis readily available in the developed and, in certain places, in the developing world. Parents may seek consultation with experienced surgeons, genetics experts, and other team members for education and decision-making about treatment.

DIFFERENTIAL DIAGNOSIS

- One of the main questions to determine in the presence of a cleft lip or cleft lip and palate is, "Does the patient have an isolated, or syndromic, cleft, which plays a major role in prognosis of treatment and genetic inheritance?" Van der Woude syndrome is a prime example, diagnosed with the presence of lip pits and means 50% subsequent inheritance.
- If cleft lip and palate are present, then 15% will be syndromic.

Syndromic Cleft Lip and Palate

- Stickler syndrome
- Robin sequence

- 22q11.2 deletion syndrome
- Treacher Collins syndrome
- Nager syndrome
- Ectrodactyly-ectodermal dysplasia
- Klippel-Feil syndrome
- Others

NONOPERATIVE MANAGEMENT

- All cleft lip patients should be treated surgically unless in extreme cases where anesthetic risk for surgery is high.

SURGICAL MANAGEMENT

- Cleft lip repair is ideally performed at 3 months of age, with the infant weighing greater than 5 kg.
- Risks of the procedure are based on the risk of the anesthetic, which is minimal.
- Main objectives of the procedure:
 - Separate the oral and nasal communication
 - Completely release and restore orbicularis oris function
 - Reconstruct the lip and nose to restore normal oral and nasal function
 - Provide an aesthetic result, which is accepted by the society and the patient
- Main steps of the procedure:
 - Mark the lip.
 - Dissect, release, and mobilize all abnormally displaced structures of the lip and nose simultaneously: muscles of the lip and base of the nose with other abnormal soft tissue attachments including alar and septal cartilage of the nose.
 - A complete tension-free closure must be achieved, or further dissection is necessary.
 - Focus on creating 3D aesthetic balance and functional harmony of the lip and nose.
- Muscle repair:
 - The muscle alignment is more important than the design of skin incision in achieving an excellent result.
 - Repositioning the muscle is one of the keys to achieving a good and stable result whether sub- or suprapariosteal, as this provides the foundation and support of the repair, maintaining alar base and nasal tip projection and

symmetry.

- To achieve complete mobilization and reconstruction, the complete release of the abnormal attachments of the muscle, and proper alignment, is key. The muscle should be vigilantly aligned.
 - Any under- or over-rotation of a carefully planned repair is usually due to a malaligned muscle repair.
- Nose repair: Correction of the nasal cleft deformity is a necessary and integral part of the primary surgery.

Preoperative Planning

- Perioperative orthopedics
 - Preoperative passive appliance: Hotz of Zurich introduced the use of an appliance placed preoperatively to control the greater and lesser segments, providing guidance for positioning the segments after lip/nose closure. This is left in place to prevent arch collapse until palatoplasty is performed.
 - Definitive scientific proof that this improves the end result is lacking. Thirty years of experience in Dallas improves the dental skeletal result, maxillary deformity, septal deviation, and other related deformities.
 - Preoperative active appliance: Nasoalveolar molding (NAM) with active preoperative segmental positioning has become internationally popular and used by many centers and teams. It provides better positioning of the maxillary segments while expanding and positioning the nasal soft tissues. It makes the surgery easier, particularly for the inexperienced surgeon.
 - Latham's earlier techniques using active forces were proven to be detrimental to maxillary growth and alignment. Adverse effects on growth need further scientific investigation before the final outcome of all active techniques is known.
 - In my experience, excellent results can consistently be obtained without adding nasoalveolar molding in the unilateral cleft lip and palate patient. The technique can be labor intensive requiring family compliance and frequent visits to the orthodontist.
 - With NAM, the molding of the nose must be done carefully to prevent creating a mega nostril through the potential tissue expansion effect, rather than just the desired reshaping of the nostril.
- Skin incision.
 - After three decades of cleft surgery, we believe that the skin incision is not very important in and of itself. The final aesthetic and functional outcome is

determined by the extended dissection that allows the surgeon to free all the anatomic elements of the lip and nose that were displaced by the cleft in order to achieve complete repositioning of these elements.

- The concept of the Salyer lip/nose repair is one of totally freeing all elements of the lip and nose in a plane above the periosteum, so they are floating free above the abnormal skeletal base.¹
- The lip and nose elements are then placed in the proper position, visualizing the 3D reconstruction and attempting to make form and function as normal as possible. The aesthetic result always remains foremost.
- Repositioning the muscle is one of the keys to achieving a good and stable result, as this provides the foundation and support of the repair, maintaining alar base and nasal tip projection and symmetry. Lining up the muscle is the single most important maneuver in the repair, and it should be vigilantly aligned.
- Various techniques today put emphasis on exact preoperative markings, which commits the surgeon. The repair should be fluid, allowing for improvisation and artistry by the surgeon, especially with respect to the nose.
- For the first 20 years, I believed that an incision around the alar base was necessary to reshape the ala; however, today, this incision has been entirely eliminated, and we feel it only adds an unnecessary scar.²

Positioning

- The infant's head is stabilized on a small donut-shaped gel headrest placed at the edge of the head of the table.
- The surgeon sits at the head of the table operating upside down with the infant's head almost in the surgeon's sterile lap slightly hyperextended to provide complete visualization of the infant's face.
- The patient is orally intubated by the anesthesiologist with a prebent tube fixed in the midline providing no distortion to the face or lip with minimal protrusion so as not to interfere with the procedure but provide safe control of the airway.

Approach

- Delaire described a subperiosteal approach with a wide dissection and incisional release of the periosteum with anatomic muscle closure.
- Supraperiosteal dissection is preferred by most plastic surgeons. We believe that the dissection above the periosteum is less detrimental to growth. Whether this philosophy is totally valid needs to be established.

- Preperiosteal dissection offers the advantage of allowing the tissue to move more easily, which is especially important in wider clefts. The analogy can be drawn to a scalp flap, which mobilizes with greater freedom when raised in a preperiosteal (ie, subgaleal) plane vs a subperiosteal plane.

TECHNIQUES

■ Salyer Unilateral Lip/Nose Repair

- Key identifiable points are marked on the lip and nose (**TECH FIG 1A**).
- The base of each ala is identified and marked using methylene blue or appropriate marking pen. The alar base on the cleft side is usually elongated and distorted compared to the normal side.
- The peak of the Cupid's bow is identified and marked on the normal side. The height of the lip, from the alar base to the peak of the Cupid's bow at rest and without tension on the noncleft side, is measured using a caliper or is just estimated.
- The height to be achieved on the cleft side is usually 6 to 11 mm and averages 7 mm in the 3-month-old.
- The midline nadir, or lowest point, of the Cupid's bow is identified and marked. An equal distance, from the height of Cupid's bow on the noncleft side to the midline of Cupid's bow, is used to identify the peak of the new Cupid's bow on the cleft side and is marked on the vermilion-cutaneous junction.
- The exact point may have to be altered a millimeter in order to have a lip that is long enough. The lip height needs to be equal to the normal side when completely dissected and placed on tension with a skin hook.
- The wet line is marked with dots along its course on the vermilion on both sides of the cleft. Identification of this line provides symmetry and improved color match of the vermilion.
- The peak of the Cupid's bow and height of the lip on the lateral lip segment are determined by the height of the lip on the normal side, based on the initial measurement. The distance along the vermilion and down the lateral lip segment may be altered according to the height of the lip desired.
- It may be necessary to go along the vermilion-cutaneous border, down the

lateral lip segment, a few millimeters more in order to create a lip, which is equal to the normal side. This may result in a shorter distance from the new peak of the Cupid's bow on the medial cleft side to the commissure of the lateral lip segment, as compared to the peak of the Cupid's bow to the commissure on the normal side.

- The proposed operation is marked with methylene blue, shown in the illustration as dots forming broken lines (**TECH FIG 1B**). The incision is marked from the peak of the Cupid's bow on the cleft side on the medial lip element and extends up and below the columella, across the base of the columella, toward the opposite normal philtrum edge, but stops just short of this landmark.

TECH FIG 1 • A. Key landmarks identified on the unilateral cleft lip/nose. **B.** Cleft lip incisions marked with *dotted lines*. An alternative technique does not extend the incision into the nose above the inferior turbinate. **C.** Initial performance of the medial and lateral lip element incisions for Salyer lip/nose procedure. **D.** Skin of lateral lip element is undermined over the orbicularis oris muscle for a maximum of 4 to 5 mm, thereby holding and freeing the orbicularis oris muscle. **E.** Preperiosteal dissection of the lateral lip element up to the infraorbital nerve using a Colorado needle. **F.** Alar base approach for dissection and release of the lateral crus of the alar cartilage and muscles of the lip from their abnormal attachment to the alar base along with freeing the nasal skin envelope to shift the cartilage, reshaping and projecting the nasal tip. **G.** Intraoperative view showing the dissection demonstrating the technique. **H.** Medial incision approach for the subcutaneous dissection of the nasal tip skin and releasing the abnormal attachment of the medial crus of the alar cartilage so the entire alar cartilage can be shifted without exposure to create nasal tip projection. **I.** Intraoperative view demonstrating the dissection and technique of the medial approach. **J.** Intraoperative view of a Keith needle with Prolene with Dacron

pledget to shape and reposition the alar cartilage and secure it while it heals. Sutures can alternately be used. **K.** Alar base cinch and alar cartilage tip sutures. **L.** Suturing of the muscle and trimming excess vermillion. **M.** Immediate postoperative view showing use of Dacron pledges (other materials may be used) for nasal reshaping with lip sutures.

- The surgeon should pull the lip down with a single skin hook and hold the lip in its new position while marking. If the incision is carried past the philtral ridge on the normal side, there is a risk that over-rotation of the lip may occur and a long lip may be created.
- The lateral lip element is marked along the cleft margin down to the newly marked peak of the new Cupid's bow (**TECH FIG 1C**). The design of the lip repair is the Salyer modification of the rotation-advancement procedure and is noted by the dotted lines. The classic incision around the alar base is not necessary and only adds scar to the final result.
- The incision on the lateral lip element continues from the vermilion-cutaneous border, and enters the nasal cavity, onto the lateral nasal wall above the inferior turbinate at the level of the piriform aperture extending to the nasal bones as necessary.
- Through this incision, the displaced and abnormally attached soft tissues of the alar base are freed from the underlying abnormal skeletal base. The incision made on the medial lip element attempts to simulate the normal philtrum, creating a normal symmetric shield-shaped Cupid's bow. The incision can be made with a no. 15 or no. 11 standard type blade, or a no. 65 or no. 67 beaver blade, which is our preference.
- The medial incision is cut through and through, including the skin and muscle; while along the vestibule of the lip, the mucosa is released and partially separated from the muscle. The medial lip element is dissected and mobilized so that it can be gently pulled down, with a skin hook, to rest at the same height as the normal side, leveling the Cupid's bow.
- The excess vermillion, containing a small amount of muscle, is left attached to the medial lip element. The lateral lip element is likewise incised, leaving an excess vermillion-muscle flap attached to it.
- These two vermillion-muscle flaps are tailored as the lip is closed and used to

produce a full pouting vermilion of the lip. This helps eliminate vermilion notching of the lip at the suture line.

- The incision of the lateral lip element is carried along the free border of the lip.
- The muscle of the lateral lip element, overlying the lesser segment, is completely freed and released above the periosteum, so the muscle can be mobilized and sutured, creating a normal anatomic muscle with nice pout to the lip (**TECH FIG 1D**). In the incomplete cleft lip, there is usually more muscle available than in the complete cleft lip.
- The orbicularis oris muscle is pulled with pickups, and the dermis is undermined 4 to 5 mm, releasing it from the underlying muscle on the lateral lip element. The operation is estimated by an experienced surgeon.
- Laterally, the point corresponding to the new peak of the Cupid's bow is marked on the border of the vermilion-cutaneous junction, along the cleft margin, at a distance equal to the future height of the lip.
- This measurement should begin superiorly on the lip, however, not in the nose, so that the skin designated for the floor of the nose is not compromised. This is an important step in achieving an adequately reconstructed nose.
- The incision on the medial lip element begins at the newly marked peak of the Cupid's bow and continues up to, but not through, the philtral column on the noncleft side.
- If the incision is continued past the philtral column on the normal side, it has the potential to create an overly rotated philtrum and abnormally lengthen the cleft side, creating disproportion to the lip as well as an obviously abnormally placed scar that no longer mimics the philtral column.
- The vermilion and muscle on each side of the lip are cut and maintained until closure of the vermilion. Excess vermilion is tailored to create fullness of the vermilion, preventing notching.
- The incision on the medial lip element is made with a no. 15 standard blade but may be performed with a no. 67 beaver blade or a no. 11 standard blade, as shown on the lateral lip element in the image.
- This incision should be made perpendicular to the skin and include the muscle, creating the C-flap, or columellar flap. This flap is used as dictated by each case when all the elements are totally freed.
- The incision on the lateral lip segment is carried through and through along the vermilion-cutaneous border, dissecting a vermilion flap for orbicularis

marginalis reconstruction. How the surgeon holds and cuts the lip determines the amount of muscle left in the vermillion.

- This lateral lip incision extends inferiorly, at least to where an adequate white roll begins, but may be continued down the lateral lip element as lip length is needed.
- The freshly cut orbicularis marginalis muscle is pulled with pickups, and the skin of the lateral lip segment is undermined from the underlying muscle for a distance of 4 to 5 mm from the edge of the incision.
- The medial lip segment is rotated downward and pulled with a skin hook until its height matches that of the noncleft side.
- The medial lip is freed from the underlying skeleton in a preperiosteal plane, using scissors. Additional dissection may be necessary to achieve adequate rotation of the philtrum and lengthening of the lip.
- Again, an opening incision above the white roll is used if additional rotation is required, and then a triangle is incorporated into the lateral lip markings. This is why the medial skin incision is always cut first.
- A Colorado needle (Stryker-Leibinger) is used to create the incision through the nasal lining just above the inferior turbinate (**TECH FIG 1E**). This provides a bloodless field for the dissection.
- Through this intranasal incision, as well as a vestibular buccal sulcus incision beneath the lateral lip element, the Colorado needle is used to dissect above the periosteum to the level of the infraorbital nerve.
- This maneuver provides for a bloodless dissection and the appropriate release of the abnormally displaced orbicularis oris muscle to provide symmetric closure. Complete preperiosteal release of the muscles facilitates complete reconstruction of the muscle of the lip.
- The beginning surgeon should be aware that the vertical height of an infant maxilla is short, and a guiding finger at skin level will ensure that inadvertent entry into the orbit is avoided as well as transection of the infraorbital nerve.
- Small curved tenotomy scissors with a round tip are inserted through the incision of the cleft-side alar base to dissect the skin from the lateral crus of the lower lateral cartilage (**TECH FIG 1F**).
- The nasal lining, if distorted, is dissected as well from the lower lateral cartilage as necessary. The nasal lining is left attached and never dissected at the region of the genu.
- The scissors are carried over the alar dome and into the subcutaneous pocket

to be created from the medial nasal approach over the tip of the nose (**TECH FIG 1G**). The intraoperative view shows the placement of the surgeon's finger as the tenotomy scissors dissect above the alar cartilage freeing the entire skin of the nasal tip on the cleft side.

- Attention is now turned to the nasal tip from the medial approach. Tenotomy scissors are placed through the medial lip incision and used to subcutaneously dissect the nasal dome (**TECH FIG 1H**).
- The scissors are inserted subcutaneously and between the medial crura, separating the skin of the nasal tip from the alar cartilage, and carried over to the nasal dome.
- The skin over the noncleft side alar cartilage is likewise freed in order to shift the nose and gain equal projection of the ala cartilages at the tip (**TECH FIG 1I**). The intraoperative photographic view shows this maneuver.
- Once all the elements of the lip and nose are totally freed, a Keith needle with Prolene suture and a Dacron pledget is used to shift the alar cartilage within the skin envelope without exposure of the cartilage to project and create a new symmetric nasal tip (**TECH FIG 1J**).
- The alar cartilage is shifted into its new position held by a surgical assistant as the surgeon places a key suture shifting the lateral orbicularis muscle.
- This may have to be repeated until the desired symmetry is achieved. It is a very important step.
- Simultaneously, a 4-0 Monocryl suture (Ethicon Inc., Somerville, NJ) is placed from below into each alar base to achieve symmetry shown by the dotted line (**TECH FIG 1K**).
- At the completion of the muscle repair with 3-0 and 4-0 chromic sutures, the orbicularis oris and pars marginalis have been positioned to provide symmetry of the lip as well as maintain projection of the nasal tip (**TECH FIG 1L**).
- The vermillion excess is trimmed until the proper volume to obtain a full lip remains, preventing notching of the free margin of the lip.
- An additional suture of nylon over Dacron pledgets is placed through the lateral ala, correcting intranasal webbing and providing additional contouring and projection of the nasal tip. Initiation of skin closure is begun with the nasal sill.
- The subdermis is closed with interrupted 6-0 PDS (Ethicon, Inc., Somerville, New Jersey).

- Mucosal closure is performed with a 4-0 chromic suture, and 6-0 nylon is used for the skin closure. Intraoperative view at completion of the Salyer lip/nose repair (**TECH FIG 1M**).
- To diminish scarring, we utilize lip taping over the scar for 3 months postoperatively, and we educate parents on how to massage the upper lip in hopes of preventing hypertrophic scarring and diminishing postoperative redness.
- Preoperative frontal view of a left unilateral complete cleft lip/nose and palate patient (**TECH FIG 2A**). Postoperative frontal view 1 year postoperative following Salyer lip/nose repair (**TECH FIG 2B**).
- Preoperative submental vertex view of the same patient (**TECH FIG 2C**). Postoperative submental vertex view 1 year postoperative of the patient (**TECH FIG 2D**).

TECH FIG 2 • **A.** Preoperative frontal view of a 3-month-old patient. **B.** Postoperative view of the same patient 1 year following Salyer lip/nose repair. **C.** Preoperative submental vertex view. **D.** Postoperative 1-year submental vertex view.

■ Triangular Skin Flap for Lengthening the Lip

- At the time of closure, when the peak of Cupid's bow on the cleft side is too high (or short), an additional technique that provides lengthening of the lip can be performed.
- This can be executed at the time of lip closure when the peak of the Cupid's bow on the cleft side is not balanced and is short by 1 or 2 mm. The dotted lines demonstrate the design of the incisions (**TECH FIG 3A**). By placing an incision 2 to 3 mm in length in the lateral lip element at a 45-degree angle 3 to 4 mm above the vermillion, a flap is created that can be advanced into an incision in the medial lip. This opens to receive the flap, which becomes triangular in shape when sutured in place. This provides 1 to 2 mm lowering of the peak of the Cupid's bow on the cleft side. This is only needed in about 30% of the time in my experience. Fisher's repair designs a triangular flap as part of the lip repair.
- The medial lip incision opens to receive the insertion of the lateral lip triangular flap, and this lengthens the lip on the cleft side (**TECH FIG 3B**). The triangular flap should be designed 3 to 4 mm above the white roll, and should not be confused with the white roll flap, which I have found to be inadequate compared to the technique described.

TECH FIG 3 • A. The design of the triangular flap is shown by dotted straight lines as marked when determined at the time of closure that the peak of the Cupid's bow on the cleft side is too high (30%). **B.** The incisions create a lateral triangular flap that is advanced into the medial lip incision lengthening the peak of the Cupid's bow on the cleft side to match the height of the normal side.

- We use this technique on innumerable occasions finding it to be quite helpful. Variations of this, first described by Bardach and now Fisher, are planned at the time of the initial marking and utilize a larger triangular flap.

This is needed in my estimation in 35% of cases and is unnecessary the rest of the time.

- The triangular flap is almost always used by Fisher and Chong and incorporated into the original planning. This provides a nicer lip with better anatomic proportions in their experience. (See Chapter 1: Anatomical Subunit Repair of Unilateral Cleft Lip.)

Noordhoff's Vermilion Flap Technique

- Another useful technique for matching the wet and dry vermilion at the time of lip closure is Noordhoff's vermilion flap.³
- This is designed along the line where the color change in the vermilion occurs between the wet and dry vermilion. Frequently, the vermilion on the medial lip element cannot be adequately matched to maintain the width of both the wet and dry vermilion at the level of the peak of the Cupid's bow, because the height of the dry vermilion on the medial lip element is inadequate.
- To correct this mismatch, a triangular flap of dry vermilion is designed from the lateral lip element and sutured into an opening created in the medial vermilion along the wet line (**TECH FIG 4A**, upper).
- This eliminates the vermilion color mismatch that occurs in the vermilion border that acts as an obvious visual indicator of an abnormal lip (**TECH FIG 4B**, lower).

TECH FIG 4 • A. An incision along the *red line* in the medial lip vermillion receives a triangular flap created from the lateral lip wet vermillion when the excess vermillion is trimmed. This provides a uniform *red line* and vermillion. **B.** Suture closure of the lip using vermilion flap of Noordhoff to increase the height of the vermillion matching the red line.

■ **Abyholm Closure of the Anterior Palate**

- Abyholm in Oslo used an anterior vomer flap closure at the time of primary lip closure. The results regarding growth produced the best results in the Eurocleft studies conducted by Semb and Shaw.^{4,5}
- This provides a simple and much less invasive approach that I highly recommend every surgeon to consider using. I use this in mission surgery where this is a good and simple technique to add to the Salyer lip/nose or whatever your preference for the lip closure.
- The technique is shown in combination with the lip closure in **TECH FIGS 5 TO 7**.

TECH FIG 5 • *Dotted line* shows lip closure with anterior vomer flap in combination with closure of floor of nose, alveolus, and anterior palate. Performing this while the lip is open facilitates closure of the anterior palate in one simple procedure, which is minimally detrimental to growth.

TECH FIG 6 • Incisions are made in the lip showing elevation of the vomer flap in the subperiosteal plane and opening of the palatal subperiosteal mucosa flap to receive it.

TECH FIG 7 • The lip is closed with sutures and the palate closed showing single layer closure of the anterior palate by fixing the mucosal or raw surface of the vomer flap below the elevated oral mucoperiosteal edge of the lesser segment creating a pocket to insert the vomer flap.

PEARLS AND PITFALLS

Age at operation

- Development of structures occurs by 3 mo or older, which is the best time to perform the operation.

Overview

- Surgeon must view the deformity as a lip/nose complex and repair both at the time of the primary repair. Technical skill and 3D

	visualization are important.
Dissection	■ All displaced and abnormally tethered structures must be completely released including the skin, cartilage, muscle, and mucosa.
3D puzzle	■ Float all structures freely in space 3D so they can be reconstructed. The biggest mistake seen repeatedly is inadequate release of the abnormal attachments of the alar base and alar cartilage medially and laterally resulting in relapse, which is really inadequate release of all the structures.
Nasal lining	■ Inadequate closure of the floor of the nose. Develop septal mucosa flap and lateral mucosa closing floor of nose as far back as possible.
Cleft nose	■ If technically capable, perform submucosal dissection of the septal cartilage, to straighten the caudal septum. ■ Create adequate skin pocket and totally free the alar cartilage so it can be translocated, shaped, and fixed.
Closure	■ Completely tension-free. The muscle is the key to the lip and nose and must be dissected, mobilized, and sutured into position setting up the lip and nose three-dimensionally.
Muscle alignment	■ Any under- or over-rotation of a carefully planned repair is usually due to a misaligned muscle repair.

POSTOPERATIVE CARE

- Routine suture line care is important. Keep the suture line clean from blood and other fluids.
- A liquid diet is recommended without the use of a nipple. Keep patient's hands and all objects away from the repair.

OUTCOMES

- Unless a simple lip repair, all cases require multiple procedures to achieve excellence, as illustrated by the patient in **FIGS 3 to 10**.⁶
- The patient underwent left unilateral cleft lip repair and primary cleft nasal repair at age 3 months, followed by palatoplasty at age 9 months. Very minor secondary lip/nose revision was required before 5 years of age. Orthodontic treatment with palate expansion was performed following eruption of the permanent first molars. This was followed by alveolar bone graft with cancellous bone at the time of eruption of the lateral canine tooth into the cleft.

FIG 3 • A. Preoperative frontal view of a 3-month-old girl with a left unilateral complete cleft lip and palate. **B.** Postoperative view after primary stage 1 Salyer lip/nose repair demonstrates a slightly larger nostril on the cleft side performed so as not to constrict the nostril, anticipating a minor secondary procedure when the patient is older. The primary lip/nose repair at age 3 months corrected the major deformity at the time of the primary operation.

- In addition to good surgical technique, a coordinated team approach is critical to achieving excellence.⁷

COMPLICATIONS

- There should be no dehiscence of any closure. Tension-free closure is important.

FIG 4 • A. Orthodontic treatment during mixed dentation stage. **B.** Demonstrates occlusion with mixed dentation before bone grafting.

FIG 5 • **A.** Frontal view after secondary cleft lip/nose repair. Stage 2. Cleft lip/nose. Stage 3. Palatoplasty. Stage 4. Cancellous bone graft. **B.** Smiling view after completion of treatment.

Section II: Cleft Palate Repair

4

Lip Adhesion

CHAPTER

Catharine B. Garland, Jesse A. Goldstein, and Joseph E. Losee

DEFINITION

- For infants with complete unilateral or bilateral cleft lip, lip adhesion is an alternative to presurgical infant orthopedics (PSIO).
- Any child with a wide complete cleft lip may be a good candidate for some form of presurgical intervention to reduce tension and optimize symmetry prior to repair.
- Presurgical interventions include the following:
 - Lip adhesion surgery, which converts a complete cleft lip into an incomplete cleft lip
 - Presurgical orthopedics such as nasoalveolar molding (passive)¹ or use of a Latham device (active)²
- Lip adhesion decreases the tension on the final repair, improves symmetry of the nasal alar bases, and restores compressive forces on the alveolar segments to assist with alignment.³ In the wide unilateral or bilateral cleft lip, this may ultimately improve the final surgical outcome.⁴

ANATOMY

- A complete cleft lip distorts both the lip and nose anatomy.
- In the unilateral complete cleft lip (**FIG 1**):
 - The orbicularis oris muscle is not in continuity. In the lateral lip element, the orbicularis oris muscle inserts vertically into the alar base and piriform.
 - The alar base on the cleft side is typically positioned laterally, inferiorly, and

posteriorly on the collapsed minor alveolar arch.

- The caudal septum and columella are deviated to the noncleft side. The medial component of the orbicularis oris muscle inserts on these structures.

FIG 1 • Unilateral complete cleft lip and nose. Note inferior, lateral, and posterior positioning of cleft side alar base and deviation of columella. (Reprinted from Kirschner RE, Adetayo OA, Losee JE. Lip adhesion. In: *Comprehensive Cleft Care*. 2nd ed. Vol 2, Chapter 41. Boca Raton, FL: CRC Press; 2016:781-791, www.thieme.com, with permission.)

- In the bilateral complete cleft lip (**FIG 2**):
 - The premaxilla is often displaced anteriorly and may be twisted or locked out of the transversely collapsed lateral maxillary segments.
 - The lateral maxillary segments are relatively repositioned and often collapsed.
 - The orbicularis oris muscle is widely separated, inserting into the alar bases at the piriform bilaterally.
 - The alar bases are laterally displaced and often asymmetric.
 - The columella is shortened.
- Normalizing some of this anatomy prior to definitive lip repair may improve the outcomes of surgery with regards to lip and nose symmetry.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The sequence of surgical intervention for a complete cleft lip depends on

individual patient and family characteristics and the surgeon and cleft center experience. This determines whether a patient undergoes a single-stage lip repair, lip adhesion prior to formal lip repair, or PSIO prior to lip repair.

- On physical examination, the width of the cleft, the presence of nostril sill tissue (a Simonart band), the relationship of the major and minor alveolar segments in the unilateral cleft lip, or the size and position of the premaxilla in the bilateral cleft lip are all evaluated carefully.
- Patient history must include an assessment of the infant's feeding and growth and identification of any medical comorbidities that may alter treatment.
- Family characteristics that factor into decision-making include financial, geographic, or other constraints. These may influence the parents' ability to frequently travel for PSIO or to be compliant with the daily care required.

FIG 2 • Bilateral complete cleft lip and nose. Note wide alar bases, short columella, and the anterior displacement of the premaxilla relative to the lateral maxillary arches.

- Determining whether an infant is a good candidate for a lip adhesion includes weighing the advantages and disadvantages with the family:
 - Lip adhesion will convert the complete cleft lip to an incomplete cleft lip and reduce the alveolar gap as well as tension on the final repair.⁵
 - Compared with nonoperative PSIO, which requires frequent office visits, lip adhesion can reduce the burden of care on the family.⁶
 - In the bilateral complete cleft lip, labial adhesion may retract the prominent premaxilla and help to lengthen the columella.⁷

- Lip adhesion incurs the additional costs of a second operation⁶ and risks of an additional general anesthetic for the infant.

IMAGING

- None needed

NONOPERATIVE MANAGEMENT

- PSIO
 - Nasoalveolar molding (NAM)¹: NAM is a passive technique that aligns the maxillary arches, narrows the alveolar gap, and molds the nasal cartilage. It is typically initiated within the first several weeks after birth. The infant must wear the device daily, and the orthodontist adjusts it weekly.
 - Latham device^{2,5}: For the protruding premaxilla, the Latham device employs active lateral movement of the maxillary alveolar segments and retraction of the premaxilla posteriorly to realign the arch form.⁷ This is a more rapid repositioning than nasoalveolar molding but does require a general anesthetic for placement of the Latham device.
- Single-stage cleft lip repair: Some authors argue that lip adhesion is an unnecessary procedure, despite the width of the cleft, and that equivalent results can be obtained in a single-stage repair.

SURGICAL MANAGEMENT

- Indications for lip adhesion include patients with wide complete clefts who are unable to undergo nonsurgical PSIO.
- Risks of surgery include infection, dehiscence, and scarring.
- In the bilateral cleft lip and palate patient with a protuberant premaxilla, lip adhesion may be combined with a premaxillary setback to optimize alignment of the premaxilla. This is typically reserved for older patients whose tissues (ie, premaxilla) are unlikely to mold under the compression of the lip adhesion alone.

Preoperative Planning

- All infants with a cleft must undergo full physical examination to rule out any concomitant cardiopulmonary disease or airway abnormalities. If additional medical problems are identified, genetic evaluation may be warranted.
- After birth, feeding evaluation is performed by instructing parents in the use of specialized bottles as needed. Weight gain is monitored weekly to ensure that

nutrition is adequate.

- A complete blood count can be performed before surgery to evaluate for anemia of infancy. After birth, hemoglobin typically reaches a nadir between 8 and 12 weeks of life in healthy term infants. In premature infants, the nadir is more profound and occurs earlier.

Positioning

- General anesthesia is induced, and the patient is intubated with an oral Rae tube, which is taped in the midline of the chin to prevent any distortion of the upper lip.
- The patient is positioned supine with the head on a small gel donut.
- Lubrication ointment is placed in the eyes.
- The face is prepared with Betadine, and sterile drapes are applied.

Approach

- Loupe magnification is used to optimize precision of the procedure.
- The markings for a formal cleft lip repair are performed, as they would be at the time of definitive repair. Key points are tattooed with methylene blue.
- Importantly, the alar bases and alar-facial grooves are marked, so that the adhesion will lead to both vertical and horizontal symmetry of these features.
- The markings for the lip adhesion are then made within the tissues that would be discarded at the time of the formal repair or within the “L” and “M” flaps.
- Some surgeons perform primary nasal repair at the time of lip adhesion, while others defer this until the time of the formal lip repair.

TECHNIQUES

■ Unilateral Cleft Lip Adhesion

Markings

- The unilateral cleft lip repair is marked and key points are tattooed. The alar bases and alar-facial grooves are marked (**TECH FIG 1A**).
- Incisions for the labial adhesion are marked within the area of the vermilion that is normally discarded on both the medial and lateral lip element. The incisions are around 10 to 15 mm in length and symmetric (**TECH FIG**

1B,C). The inferior half of the incision is performed on the upper lip, and, the superior half is performed on the nasal floor—truly making this a “lip-nose adhesion.” On the medial lip element, the midpoint of the incision is centered at the columellar-lip junction. On the lateral lip element, the alar base denotes the midpoint of the incision. The position of these incisions is critical for alignment of the alar base. *The alar base must be symmetric with the contralateral side in both the horizontal and vertical plane*, or an asymmetric adhesion and repair will be performed and will make the subsequent definitive cleft lip and nose repair more challenging.

- The lateral buccal sulcus incision is marked to mobilize medially of the lateral lip element and ultimately a tension-free adhesion. This incision is carried up around the piriform aperture to just above the inferior turbinate (**TECH FIG 1D**).

Incision and Dissection

- Epinephrine is infiltrated into the incisions.
- Incisions are made using a number 15 blade or ophthalmic knife.
- The buccal sulcus incision is dissected in a suprapariosteal plane. The alar base is released from the piriform rim and the lateral lip element is widely mobilized to reduce tension on the adhesion.
- During this mobilization, some surgeons may continue their lateral dissection up and over the lower lateral cartilage if they plan to perform primary nasal repair at the time of adhesion.
- The adhesion incisions on the medial and lateral lip elements are then made. The skin and mucosa are dissected to expose the orbicularis oris muscle.
- In the medial lip element, the dissection is carried toward the anterior nasal spine. Here the quadrangular cartilage is found displaced away from the cleft (**TECH FIG 2A**). The caudal septum may be repositioned now, rather than at the time of definitive lip repair. The quadrangular cartilage is released from the anterior vomer at the anterior nasal spine (for about 1 cm). This allows the caudal septum to be repositioned to the cleft side of the anterior nasal spine (**TECH FIG 2B**).

Suturing

- The septum is brought back to the midline, and it is sutured into place using a 4-0 Monocryl suture.

- A 2-0 Prolene horizontal mattress retention suture (single armed on a large needle) is placed in the orbicularis oris muscle. This stitch begins at the inferior end of the lateral lip incision (**TECH FIG 3A**). It is passed in a subcutaneous plane laterally into the cheek, then deep through muscle, and exits in the buccal sulcus laterally (**TECH FIG 3B**). The Prolene suture is then passed back through the same exit site and is passed in the submucosal plane out through the superior end of the lateral lip incision (**TECH FIG 3C**). Care is taken to ensure that the skin does not dimple with this stitch. The process is repeated on the medial lip element, from superior to inferior (**TECH FIG 3D,E**). The stitches exit on the inferior aspect of the lip adhesion incisions on both sides (**TECH FIG 3F**). As much of the orbicularis oris muscle is captured in the loops of the sutures as possible (**TECH FIG 3G**). This allows the medial and lateral lip elements to be approximated through the orbicularis muscle (**TECH FIG 3H**). The ends of the suture are clamped and tied later.

TECH FIG 1 • A. Preparation for a unilateral lip adhesion. An oral Rae endotracheal tube is positioned in the midline and taped into place. The markings for a

unilateral cleft lip and nose repair are marked and tattooed, including the alar bases. The lip adhesion incisions are made within the tissue that would normally be discarded. Design of the lip adhesion incisions on the **(B)** medial and **(C)** lateral lip elements. **D.** An upper buccal sulcus incision is carried up around the piriform aperture over the inferior turbinate. (Reprinted from Kirschner RE, Adetayo OA, Losee JE. Lip adhesion. In: *Comprehensive Cleft Care*. 2nd ed. Vol 2, Chapter 41. Boca Raton, FL: CRC Press; 2016:781-791, www.thieme.com, with permission.)

TECH FIG 2 • Repositioning the caudal septum. **A.** The anterior nasal spine and caudal septum are deviated away from the cleft in the native position. **B.** After the caudal septum is separated from the anterior nasal spine, it may be repositioned (forceps are mobilizing the septal cartilage).

- As the lateral lip element is advanced, the buccal sulcus incision back cut is closed with interrupted 4-0 chromic sutures.

TECH FIG 3 • Placement of the internal retention suture. **A.** The suture is passed through the inferior aspect of the adhesion incision. **B.** After capturing the muscle, it exits laterally through the oral mucosa. **C.** The needle is placed back through the same exit site to exit through the superior part of the adhesion incision. **D,E.** The process is repeated on the medial lip element. **F,G.** The orbicularis oris muscle is captured in the loop of suture on both sides of the cleft. **H.** The ends of the suture are pulled together. The tension placed on a wide swath of orbicularis oris muscle reapproximates the lip and nose. (Reprinted from Kirschner RE, Adetayo OA, Losee JE. Lip

adhesion. In: *Comprehensive Cleft Care*. 2nd ed. Vol 2, Chapter 41. Boca Raton, FL: CRC Press; 2016:781-791, www.thieme.com, with permission.)

- The deep/posterior edge of the mucosal incision is then closed using interrupted 5-0 Vicryl sutures. Half of this suture line makes up the floor of the nose, and half makes up the superior lip.
- The Prolene suture is tied down, and care is taken to bury it into the muscle.
- The edges of the orbicularis oris muscle are approximated with three 4-0 Monocryl sutures.

Completion

- The anterior edge of the adhesion incision is closed last with interrupted 5-0 fast-absorbing plain gut sutures (**TECH FIG 4A**)
- If nasal repair is planned with the lip adhesion, this is performed now. The senior author, however, uses postadhesion nasal stents to mold the nose during the healing process and *defers* the rhinoplasty to the time of definitive cleft lip-nose repair. At that time, our preferred technique is open primary rhinoplasty through rim incisions to expose and reposition the lower lateral cartilage.^{8,9} A Tajima, inverted-U rim incision is utilized on the cleft side of the nose.
- Duoderm is placed on the cheeks bilaterally. While bringing the cheeks together, a Steri-Strip is placed across the lip to additionally take tension off the repair.
- Our practice is to use nasal conformers postoperatively to optimize nasal symmetry. These conformers are sized in the operating room (**TECH FIG 4B**) and subsequently taped into place (never sewn) and used daily by the parents at home in the months between lip adhesion and definitive lip repair (**TECH FIG 4C**).

TECH FIG 4 • **A.** Completion of unilateral cleft lip adhesion and **(B)** sizing of nostril conformers. **C.** The nostril conformers are taped into place and worn daily in the postoperative period after both the lip adhesion surgery and after definitive lip and nose repair, as shown here. (Reprinted from Kirschner RE, Adetayo OA, Losee JE. Lip adhesion. In: *Comprehensive Cleft Care*. 2nd ed. Vol 2, Chapter 41. Boca Raton, FL: CRC Press; 2016:781-791, www.thieme.com, with permission.)

■ Bilateral Cleft Lip Adhesion

- The bilateral cleft lip repair is marked and key points are tattooed (**TECH FIG 5A**).
- The incision for the adhesion is marked on both sides of the prolabium at the junction of the skin and mucosa, approximately 10 to 15 mm in length (**TECH FIG 5B**). The incision is centered at the junction of the columella and prolabium, such that half of the incision is on the prolabial lip element and half is intranasal.
- The lateral lip incisions are marked in the part of the vermilion that would normally be discarded or used as a “C” flap. These are also centered at the alar base, such that half of the incision is on the lip vermilion and the superior half is within the nose. The incisions are drawn so that the alar bases will be positioned symmetrically when the lip-nose adhesion is completed (**TECH FIG 5C**).
- Epinephrine is infiltrated into the incisions and these are made with a number 15 blade or ophthalmic knife. The orbicularis oris muscle is exposed

in the lateral lip element bilaterally.

- The buccal sulcus incision on both lateral lip elements is marked and carried into the nose, around the piriform rim, and above the inferior turbinate. Supraperiosteal dissection is performed to completely release the lateral lip and alar base from the maxilla and piriform rim so that they may be advanced to reach the premaxilla.

TECH FIG 5 • A. Preparation for bilateral cleft lip adhesion begins with marking the bilateral cleft lip repair. Bilateral lip adhesion markings on the **(B)** prolabium and **(C)** lateral lip elements.

- A 2-0 Prolene retention suture is placed in the orbicularis oris muscle. This is performed similar to the unilateral case (see **TECH FIG 3**). The stitch begins at the inferior end of the lateral incision on the left side. It is passed in a subcutaneous plane laterally into the cheek then deep through muscle and exits in the buccal sulcus laterally. It is then passed back through the same exit site in the submucosal plane to exit the incision at the level of the nasal sill. Care is taken to ensure that the skin does not dimple with this stitch. After capturing the orbicularis muscle on one side, the suture is passed deep across the premaxilla in a preperiosteal plane, at the level of the nasal sill. This exits through the contralateral prolabial incision at the level of the nasal sill. The process is repeated on the right side, with the suture capturing the right orbicularis muscle, entering through the lateral incision at the level of the nasal sill, and exiting at the inferior margin. The suture is again passed deep across the prolabium through the inferior margins of the prolabial incisions. Once positioned, the ends of the suture are clamped. With tension through the orbicularis oris muscle, this suture brings the lateral lip elements to meet the prolabium.

- The posterior edge of the mucosa is closed with 5-0 Vicryl suture from the superior/nasal end of the incision down toward the inferior/labial end on both sides.
- The 2-0 Prolene suture is tied down and the knot is buried in the lateral muscle.
- Additional 4-0 Monocryl sutures are placed to secure the orbicularis oris muscle to the prolabium on each side.
- The anterior skin incisions are then closed using interrupted 5-0 fast-absorbing plain gut sutures.
- At the completion of the closure, the markings for the C flap and nasal sill on both sides should be perfectly lined up such that the alar bases are symmetric in both the vertical and horizontal planes (**TECH FIG 6**).
- Duoderm is placed on each cheek. While bringing the cheeks together, a long Steri-Strip is placed across the labial adhesion to reduce tension on the repair.

TECH FIG 6 • Bilateral complete cleft lip after premaxillary setback and lip adhesion (**A**) anteroposterior and (**B**) worm's-eye views.

■ Premaxillary Setback

- In the infant who is older than 6 months, the vomer is likely to be ossified. In these cases, a protuberant premaxilla will be unlikely to move when subjected to the forces of lip adhesion alone. In these cases, we will typically perform a premaxillary setback at the time of lip adhesion.

- A 10 mm vertical incision is marked along the anterior vomer, just posterior to the premaxillary segment (**TECH FIG 7A**).
- The periosteum is elevated off the vomer bilaterally to the level of the quadrangular cartilage.
- A closing wedge osteotomy is designed behind the premaxilla, and a small rongeur is used to remove this bone (**TECH FIG 7B**). No cartilage is removed. The closing wedge osteotomy is noted to be sufficient when the premaxilla can be repositioned posteriorly and in good alignment with the lateral alveolar segments (**TECH FIG 7C**).

TECH FIG 7 • Premaxillary setback. **A.** The incision is marked on the vomer just behind the premaxilla. **B.** After dissecting in a subperiosteal plane, rongeurs are used to create a closing wedge osteotomy. **C.** The premaxilla is repositioned in alignment with the lateral maxillary arches and affixed with 4-0 PDS sutures.

- A 4-0 PDS is sufficient to fixate the premaxilla into its new position, promoting bone-to-bone contact. This is secured from the premaxilla to the posterior vomer. Additionally, on each side, a 4-0 PDS suture can be passed directly through the mucosa of the lateral premaxillary alveolus and through the medial edge of the lateral arch alveolus (as an external stitch). When tied, this will secure the repositioned premaxilla to the lateral segments during healing.
- The vomer incision is closed using a running 5-0 Chromic gut suture.
- Combining a premaxillary setback and bilateral lip adhesion, as described herein, will not compromise the perfusion of the premaxillae. The authors do not perform a premaxillary setback and complete bilateral cleft lip and nose

repair, rather stage the late presenting patient with: stage 1: premaxillary setback and lip adhesion. Stage 2: complete cleft palate repair. Stage 3: complete cleft lip and nose repair.

PEARLS AND PITFALLS

Timing	■ Optimal timing is at 2 months of age.
Incisions	■ Incisions must be placed in tissue that will be discarded at the time of definitive lip repair. ■ Therefore, the markings for a definitive lip repair are performed first.
Permanent retention suture	■ A permanent suture is placed through the orbicularis oris muscle on both sides of the cleft. ■ It must capture a large swath of orbicularis oris muscle on both sides in order to reduce tension on the lip adhesion and decrease the risk of dehiscence.
Alar base positioning	■ Symmetrical placement of the alar bases during the lip adhesion is critical. ■ Alar bases must be symmetric in both the horizontal and vertical planes. ■ If the alar bases are asymmetric at the completion of lip adhesion, this deformity will be more difficult to correct at the time of definitive cleft lip repair.
Nasal stents and conformers	■ The use of nasal conformers after lip adhesion helps to lengthen the columella and mold the lower lateral cartilages to optimize nasal form prior to definitive lip repair.

POSTOPERATIVE CARE

- The patient is admitted postoperatively for monitoring and typically discharged home the following day if oral intake is adequate to maintain hydration.
- Patients may return to their usual bottle-feeding.
- Elbow splints are typically used to prevent inadvertent injury to the repair.
- Steri-Strips are utilized and can be replaced for 2 weeks following surgery to take tension off of the repair.

- Nasal conformers are used postoperatively. The parents are taught how to clean and replace the stents daily. If the adhesion was performed under more tension than desired, or if there is a tenuous soft tissue closure, nasal stenting can be started in 1 to 2 weeks after adequate healing has occurred.
- The nasal conformers are increased in size as the infant grows over the next 3 to 4 months.
- Definitive cleft lip and nose repair is then performed in 3 to 4 months, at approximately 6 months of age. At the time of the repair, the adhesion scar is excised and the permanent retention suture is removed.

OUTCOMES

- Labial adhesion has been shown to increase the vertical height of the medial and lateral lip elements in unilateral cleft lip¹⁰ and increase the bulk of orbicularis oris muscle tissue for closure and reconstruction of the philtral ridge.¹¹
- The adhesion of the orbicularis oris muscle molds the alveolar segments and reduces a wide alveolar gap by approximately 60% in both unilateral and bilateral cleft lips.^{3,12} If gingivoperiosteoplasty is planned, however, passive alveolar molding may still be required to align the maxillary segments.

COMPLICATIONS

- Dehiscence: Either partial or total dehiscence occurs between 4% and 17% of the time.^{6,10,12} Dehiscence is more common in the bilateral than the unilateral complete cleft lip, because the bilateral lip (without premaxillary setback) is often under more tension. Partial dehiscence may not require operative intervention if some of the alignment is maintained.
- Scarring: Scarring of the lip can occur, and some authors report that it can interfere with the final repair. When the incisions are planned carefully, however, the scarring will only occur in tissues that would normally be discarded at the time of definitive lip repair.

CHAPTER Bilateral Cleft Lip Repair

John A. van Aalst

DEFINITION

- A cleft of the lip occurs when the maxillary prominence fails to fuse, first with the lateral nasal prominence and then the medial nasal prominence; when this failure of fusion occurs bilaterally, a bilateral cleft deformity is the result.¹
- Cleft lip occurs most commonly in patients from Southeast Asia and the southwestern United States (1/250 to 1/400 live births), is less common in Caucasians (1/1000), and is least common among African Americans (1/2000).¹

ANATOMY

- Bilateral clefts of the lip involve the tissues of the primary palate. This includes the skin, muscle, and mucosa of the lip and the alveolus, extending posteriorly to the incisive foramen.
- The premaxillary segment contains the central alveolus (maxilla) with the tooth buds of the central incisors; this bone is attached to the vomer, the bony underside of the septum.
- The premaxillary segment presents with variable anterior flaring, which may have variable presentation: it may be very anteriorly positioned or may be correctly positioned within the maxillary arch.
 - A complete bilateral cleft is likely to have significant anterior flaring, whereas the premaxillary segment of an incomplete cleft is likely to be positioned correctly between the lateral segments of the maxilla.
- Gingiva and mucosa cover the bone of the premaxillary segment and then transition to skin; this segment does not contain true lip vermilion. The skin is generally circular in shape and is without a true white roll. No muscle is

present in this region (except in incomplete clefts, where the muscle is in continuity with the lateral lip elements).

- Lateral segments of a bilateral cleft lip have all of the elements of the lip present lateral to the nasal ala (wet vermilion, dry vermilion, white roll, skin, and muscle); moving medially, the fullness of each of these components diminishes as the lip structures narrow and ascends toward the cleft of the nose.

PATHOGENESIS

- Lip fusion occurs on day 42 of gestation.
- Fusion may be interrupted secondary to genetic causes (MSX1 gene anomaly), environmental causes (including medications—steroid, anticonvulsants, retinoic acid—alcohol, tobacco use), or a combination of the two (alcohol consumption and cigarette use in the face of an MSX1 genetic anomaly).¹
- The medial migration of the maxillary prominence is arrested, leading to failure of fusion with the medial and lateral nasal prominences; failure of fusion of these latter two leads to clefting of the nostril floor.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Many children with bilateral cleft lip will be diagnosed in utero, prompting a prenatal visit with cleft team members, including the surgeon. The cleft team member describes the concept of team care to the family, the needs of the child immediately following birth, and the surgical preparation for cleft lip repair at approximately 3 months of age.
- Patient history should include the presence of family members with clefting; maternal exposure risks: cigarette and alcohol use; medications, including anticonvulsants and steroids; and folic acid supplementation during early pregnancy.¹
- Following delivery, the first visit to the surgeon is generally within the 1st week of life.
- In addition to a full physical examination, the tailored examination of the face detects whether the cleft is complete or incomplete, whether there is asymmetry between the two sides, and whether the premaxilla is proclined (**FIG 1**). In addition, the presence of clefts of the alveolus and of the palate must be documented.

FIG 1 • Infant with bilateral cleft lip. Figure **A** demonstrates a frontal view of an infant with a bilateral complete cleft lip and palate; the premaxilla is anteriorly positioned (proclined). Figure **B** is a worm's eye view of the same infant, demonstrating the asymmetry of the cleft, with the premaxilla positioned more to the patient's left. As can be noted more clearly in this figure, the patient also has a cleft of the alveolus and palate.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- No routine imaging studies are required for children with bilateral cleft lip prior to surgical repair.
- Because these children may have other congenital anomalies, additional findings on physical examination will dictate the need for additional diagnostic studies.
- If the child has evidence of breathing difficulties, or sleep apnea, a sleep study may be warranted. If there is any evidence of feeding/swallowing difficulties with concerns about aspiration, a swallow study may be warranted; if other cranial abnormalities are present, a craniomaxillofacial computed tomography scan may be warranted.

NONOPERATIVE MANAGEMENT

- Although nonsurgical management of the bilateral cleft lip is not appropriate, presurgical management for control of the proclined maxilla is recommended.
- The proclined maxilla can be treated with a simple taping regimen (**FIG 2**), with nasoalveolar molding^{2,3} or actively with a Latham device^{4,5} to direct position of the alveolar segments prior to surgical repair.

SURGICAL MANAGEMENT

- Children are judged ready for surgery using the rule of 10s: approximately 10 lb (4.5 Kg), 10 week of age, and a hemoglobin count of 10.⁶⁻⁸
- If there are any other symptomatic comorbidities or concerns about appropriate weight gain, delay in surgery is warranted.

Positioning

- At the time of surgery, the child is positioned in the supine position and intubated with an oral Ring-Adair-Elwyn (RAE) tube (**FIG 3A**).
- A shoulder roll is placed to obtain gentle extension of the neck.
- The entire face is prepped and draped, and a throat pack is placed.
- Markings are made for lip repair with tattooing of key landmarks (**TECH FIG 1**).
- Local anesthetic with epinephrine is injected following the markings.

FIG 2 • Preoperative preparation of the patient in **FIG 1** with a taping regimen. This taping regimen needs to start shortly after birth to maximize the effect on premaxillary segment retroclining (an early start is also true for other forms of presurgical orthopedics, including nasoalveolar molding). **A.** During the taping regimen. **B.** At completion of the taping regimen. **C,D.** Immediate preoperative photographs demonstrate an improved position of the premaxilla in a more symmetrical position after taping regimen.

FIG 3 • A. The patient is positioned supine and intubated with an oral RAE tube, with taping on the chin so that the upper lip is not distorted. **B.** Landmarks. The central philtral column with skin (a) is 2 mm wide at the waist and 2 mm from low to high point of Cupid's bow. The lateral flanking de-epithelialized regions (b) are also 2 mm wide. The remnant skin and mucosa of the premaxillary segment have been incised into three parts. These areas are labeled (e) bilaterally and (f) centrally and inferiorly. At the superior philtral column (b-a-b) are extensions of skin (c) that will be eventually be used to close the floor of the nose. The central flap (f) is used to reconstruct the central upper buccal sulcus; the two lateral flaps (e) are turned out laterally and used to reconstruct the anterior surface of both alveolar clefts. Bilateral upper buccal sulcus incisions (d) allow medialization of cheek tissue to minimize tension at final closure. The vertical component of the incision is made medial to Stensen duct (the greater the height of this incision, the greater the capacity to medialize cheek tissue). The horizontal incision is made at the junction of the gingiva and oral mucosa to the base of the L flap (without injuring the L flap). A Freer

elevator is used to lift the periosteum from the maxillary surface, exposing the infraorbital nerve. The region of the nerve is the most significant area of tethering, which prevents medial movement of cheek tissue. The periosteum medial and lateral to the nerve is cut vertically, avoiding injury to the nerve and releasing the tethering effect of the periosteum.

TECHNIQUES

■ Markings

- The two most commonly used techniques to repair the bilateral cleft lip are the Millard technique⁶ and the Mulliken technique.⁷⁻¹⁰
- Based on modifications of the Mulliken technique, markings for the neophiltrum include the following:
 - 2 mm at the waist (at the junction of the columella with the premaxillary skin; **TECH FIG 1**)
 - 2 mm between the low and high points of Cupid bow
 - Flanking de-epithelialized regions, each 2 mm wide and the same height as the philtral column
- The three-part division of the premaxillary mucosa is marked.
- The bilateral advancement flaps are marked, with 2 mm of intact white roll retained with the vermilion component on both sides, with as much as possible skin conserved, but avoiding vermilion (see **TECH FIG 1**).
- Bilateral upper sulcus-releasing incisions are marked:
 - The vertical component is medial to Stensen duct.
 - The horizontal component is marked at the junction of the gingiva and upper buccal sulcus mucosa, extending medially to the edge of the L flap.

TECH FIG 1 • Attention to detail in the markings is key to an aesthetic outcome. Before making the marks, take note of the asymmetries present. Markings are made before injection of local anesthetic, and the points are tattooed into tissue with a 30-gauge insulin needle using either Bonnie blue or methylene blue. The high and low points of Cupid's bow are 2 mm wide; the waist of the philtral column is also 2 mm wide. The flanking regions that will be de-epithelialized on either side of the philtral column skin are also 2 mm in width. At the superior lateral position of the two areas marked for de-epithelialization, there should be a horizontal extension along the skin, which will be used for eventual closure of the nostril floor. The lateral lip markings begin with the medial marking for the white roll. This point should be marked at the medial-most position of full (complete) white roll (moving further medial from this position, the white roll tapers); a second point is marked 2 mm lateral to the first point. The medially curved line on the vermilion has its furthest medial extension at the junction of dry and wet vermilion; the 2 mm of white roll will remain with the vermilion and be used to reconstruct the white roll under the philtral column (also 2 mm in width). The

upper buccal sulcus—releasing incisions are also tattooed so the marks continue to be visible despite oral secretions or bleeding (shown in **FIG 3B**).

■ Incisions

- The neophiltrum is incised with de-epithelialization of the two flanking regions. These three regions are lifted as a single unit (**TECH FIG 2A**), improving blood supply to the philtral skin.
 - The three parts of the premaxillary mucosa are incised (see **TECH FIG 2A**). The central portion is used to reconstruct the upper buccal sulcus (**TECH FIG 2B**).
 - The lateral two flaps are used to provide coverage over each of the alveolar clefts (**TECH FIG 2C,D**).
- The advancement flap is incised, starting laterally, at the white roll, leaving 2 mm of intact white roll with the dry vermilion (see **TECH FIG 2B–D**), extending along the junction of skin and vermilion (carefully avoiding inclusion of vermilion with the skin flap).
 - The incision is then extended inferior to the nose, then laterally, along the crease between the nose and lip, but not extending beyond the alar margin (see **TECH FIG 2C,D**).
- The lateral vermilion flap (L flap) is incised, leaving excess dry and wet vermilion for lip reconstruction (this helps to create a pout of the central lip).
 - The inferior part of the incision is continued on the mucosal side toward the alveolus in a line parallel to the advancement flap incision.
- At the superior-medial incision of the advancement flap, the L flap incision is extended into the nose at the junction of skin and mucosa, extending toward the inferior turbinate.
- The skin margin of the advancement flap is then separated for 3 to 4 mm from the orbicularis oris muscle (during reconstruction, this separation will allow approximation of the muscle as a separate layer; see **TECH FIG 2D**).
- Next, the lateral releasing incision is made in the upper buccal sulcus: the vertical component is made 1 cm medial to the Stensen duct, extending down to the junction of the oral mucosa and gingiva; the horizontal component is then incised along the junction of the oral mucosa and gingiva, to the base of the L flap (see **FIG 3B**).

- Using the lateral releasing incision, maxillary tissue is dissected from the maxilla in a subperiosteal plane with a Freer elevator. The infraorbital nerve is identified.
- The periosteum is incised medial and lateral to the nerve, allowing medialization of cheek tissue.
- The right angle of the releasing incision can now be extended medially to decrease tissue tension during closure.

TECH FIG 2 • A. Incisions for bilateral cleft lip. A beaver blade is used to make all incisions. At the skin markings, part of the tattooed mark is maintained on the retained flap in order to clarify positioning of the flaps at final closure. **B.** Lifting of the philtral flap with flanking de-epithelialized regions. Note the inset of the central premaxillary mucosal flap to the periosteum of the premaxillary segment with a central stitch; this

reconstructs the central upper buccal sulcus. Closure of the right nostril floor with the L flap and the right turnover flap from the premaxilla. These two flaps are sutured to each other, simultaneously closing the nostril floor and the anterior surface of the alveolar cleft ((**C**) on the **left**, (**D**) on the **right**). Note that the nostril orifice is maintained despite approximation of these flaps.

■ Reconstruction

- The L flap is inset into the floor of the nose using 5-0 chromic with the intact mucosa facing down toward the oral cavity and raw surface up toward the lip (see **TECH FIG 2B–D**).
- The lateral premaxillary flaps are turned over (intact surface down) and sutured with 5-0 chromic to the periosteum of the maxilla at the lateral base of the L flap.
 - The two flaps are then sutured to each other, to close the floor of the nose.
- A 4-0 PDS is used as an alar cinch suture (**TECH FIG 3A**), setting the alar margins at the medial canthi bilaterally (**TECH FIG 3B**).
- Oral mucosa is reapproximated at the medial-most extension of the releasing incision (medializing tissue that was at a right angle into a straight line) using 4-0 and 5-0 chromic interrupted sutures.
- Muscle is approximated using 4-0 PDS interrupted sutures with buried knots (**TECH FIG 3C**).
- The dry vermillion and white roll are approximated with 5-0 plain interrupted sutures (**TECH FIG 3D**).
- The neophiltrum is inset with 6-0 Monocryl deep dermal suture at the lateral margins of the flap, which correspond to the high points of Cupid's bow, followed by 6-0 plain suture at the skin.
- 6-0 plain sutures are placed from philtrum to vermillion between the high and low points of Cupid's bow. 6-0 Monocryl is used for deep dermal closure along the philtral column.
- 7-0 PDS subcuticular stitch is used to close the skin. The nostril floor is closed using 5-0 chromic suture (**TECH FIG 3E**).

- Dermabond or Steri-Strips are applied to the lip incisions.

TECH FIG 3 • The alar cinch suture (which sets the lateral ala at the medial canthus bilaterally) is placed on the underside of the alae of the nose **(A)** and is used to set the lateral alae at the medial canthi bilaterally **(B)**. Importantly for the lip repair, positioning the base of the nose begins the process of medializing tissue to close the lip. **C**. Muscle closure is performed using 4-0 PDS interrupted buried sutures. Reapproximation of muscle must be accomplished throughout the full extent of the lip. The philtral tissue is visualized from the underside ((a) with skin and bilateral (b) regions that are de-epithelialized). The de-epithelialized regions will be placed under the skin advancement flaps (c) and will provide fullness in the lateral philtral column bilaterally. The philtral flap will

be inset at (d) bilaterally for final closure. Note the white roll (e) at the medial superior area of vermillion. The areas of white roll (e) will be approximated to each other. **D.** Reapproximation of the white roll with dry vermillion prepares for inset of the philtral column. **E.** Final closure of the lip.

■ Variations in the Technique

- The same technique can be used in older patients requiring correction of a wide philtrum (**TECH FIG 4**).
- Though the author's preferred sutures are delineated in this chapter, multiple sutures can be substituted during various junctures of the repair. For example, 4-0 Vicryl can be substituted for 4-0 PDS for reapproximation of the muscle.
- Although the width of philtral column skin flap in a 3-month old patient is recommended as 2 mm from low to high point of Cupid's bow, and 2 mm at the philtral waist (abutting the nasolabial junction), surgeons may choose to incorporate the flanking de-epithelialized regions (also approximately 2 mm wide) into the actual skin-based philtral flap, thereby increasing the width of the skin.

TECH FIG 4 • A 9-year-old with previous bilateral cleft lip repair. **A,B.** The high points of Cupid's bow are elevated bilaterally because the entire skin paddle of the premaxillary segment was used for lip repair. Retained mucosa of the premaxillary segment is present; the patient has a wide philtrum due to use of the central maxillary skin and mucosa as a vermilion substitute. The white roll remains laterally displaced. **C.** Markings have been made for repair of the cleft lip with central philtral column, flanking de-epithelialized regions, scar excision, and premaxillary segment mucosa excision. **D.** Final closure at revision surgery.

Physical findings	■ Be cognizant of asymmetries on initial examination; they may be correctable by presurgical molding techniques; if not, they must be accounted for during initial lip markings. ■ Retroclining the premaxilla is key to improving lip repair outcomes. ■ Failure to retrocline the prominent premaxilla often results in lateral maxillary arch collapse, thereby “locking out” the premaxillary segment in its abnormal anterior position. If this occurs, the premaxilla cannot be positioned properly until maxillary expansion is initiated, which is usually done during the phase of mixed dentition.
Markings	■ Make the philtral column as long as possible on the premaxillary skin. ■ An appropriately narrow philtral column avoids a too-wide philtrum with continued facial growth. ■ Borrowing white roll from the lateral lip segments is crucial because true white roll does not exist at the skin margin of the premaxillary segment. ■ Provide extra fullness in the central vermilion to avoid a whistler’s deformity.
Incisions	■ Avoid the mistake of making the incisions on the lateral lip elements too medial. This will make the height of the lip incongruent with the philtral column height.
Closure	■ Closure with tension is the primary cause of muscle dehiscence and scar widening. ■ Releasing incisions in the upper buccal sulcus provide tension-free closure. ■ If tension persists, re-examine the releasing incisions for further release in areas of periosteal banding. ■ Muscle closure should be performed along the full height of the lip.
Postoperative care	■ No change in feeding regimen is needed after surgery. ■ Scar massage at 1 mo

POSTOPERATIVE CARE

- Postoperative in-hospital stay is optional.
- Arm restraints should be considered.
- Gentle narcotic use for pain is recommended.

- Undertreatment of pain may hinder the child's ability to feed.
- Overtreatment can lead to constipation.
- Breast or bottle feeding is initiated in the recovery room following completion of surgery.

OUTCOMES

- Ideally, primary repair of the bilateral cleft lip should result in a symmetrical, aesthetically pleasing repair that does not require revision (**FIG 4**).

FIG 4 • The child in **FIGS 1** and **2** is shown at 1 month (**A**) and 4 months (**B**) after surgery.

- However, the reality is that revisions are often needed (**TECH FIG 4** and **FIG 5**).
- Timing for revision is controversial. Times for possible lip revision:
 - 5 years of age, on entry into kindergarten
 - Life changes, including transfer to a new school

- Timed with other surgeries, such as speech surgery or bone grafting
- After skeletal maturity following orthognathic surgery

COMPLICATIONS

- Early
 - Bleeding
 - Dehiscence of the repair, either partially or totally
 - Loss of the neophiltral column
 - Stitch spitting/abscess
 - Rarely, infection
- Late
 - Scar widening, including the philtrum becoming too wide in proportion to the overall size of the lip
 - Asymmetry: the most noticeable asymmetries are of the Cupid's bow, with one high point being higher than the other
 - Poor animation because of muscle dehiscence or heavy scar burden

FIG 5 • Postoperative results of the lip revision shown in **TECH FIG 4**. The patient is seen in a frontal view (**A**) and a worm's eye view (**B**). Note that the patient has improved philtral width, Cupid's bow, and wet with dry vermilion balance.

Secondary Deformities

CHAPTER

Catharine B. Garland, Jesse A. Goldstein, and Joseph E. Losee

DEFINITION

- After cleft lip and nose reconstruction, secondary deformities of the lip and nose are common. The actual incidence of deformity is difficult to quantify because of individual variability in assessing what constitutes a deformity. For example, the incidence of revisionary surgery ranges from 0% to 100%.¹
- Asymmetries leading to deformity can be encountered anywhere along the lip-nose complex. These are caused by inadequate tissue in some cases and excessive tissue in others.
- This chapter focuses on addressing secondary cleft lip deformities rather than secondary cleft rhinoplasty. Correcting asymmetries of the alar bases, however, is often an important component of secondary lip revision surgery.

ANATOMY

- The ideal lip and nose complex is composed of the following features:
 - A symmetric nostril shape, with symmetric nostril sills and alar base position
 - A balanced Cupid's bow with a smooth curve to the vermilion border
 - Symmetric philtral columns with a well-defined philtral dimple²
 - Smooth contour and balance of the mucosa
 - A central pouting tubercle in the vermilion
 - A functional orbicularis oris muscle sling that leads to symmetry with animation
 - Appropriate tooth show at rest

PATHOGENESIS

- Some secondary deformities are intrinsic, such as the nasal deformity

characterized by a hypoplastic and flattened lower lateral cartilage.

- Other deformities are iatrogenic from the primary cleft repair. These include deformities caused by scarring, inadequate correction, an unbalanced reconstruction, or altered growth and development.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most important part of the history is to ascertain what bothers the patient and the family. This may not always be congruent with what the surgeon sees as the most significant deformity. Realistic expectations of operative intervention must be discussed preoperatively.
- The physical examination must include a careful analysis of the deformity. The reconstruction is then tailored to address the specific anatomic abnormality.
 - Are the alar bases symmetric in shape and position? They must be symmetric in the vertical, transverse, and sagittal plane.
 - What is the nature of the cutaneous scar? Assess whether the scar is hypertrophic, atrophic, or pigmented. This helps to inform the surgeon about the patient's innate healing response.
 - Is the philtrum well defined and symmetric?
 - Is Cupid's bow balanced or is there a discrepancy in height on the cleft side? Are the vermilion border and white roll congruous structures?
 - Is the red line, wet-dry junction, in alignment? An excess of wet mucosa in a region that should be composed of dry vermilion often causes persistent chapping of the lip in that area.
 - Is there adequate lip length and appropriate tooth show? Is the buccal mucosa scarred and tethered?
 - Is the mucosa symmetric? Is there excess mucosa on the cleft side or deficient mucosa at the central tubercle? Is there a notch in the mucosa at the site of repair?
 - Is the lip symmetric in animation? Bunching of the lip may suggest dehiscence of the orbicularis oris muscle.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative workup is per hospital routine.
- Under anesthesia, a careful analysis of the lip and nose is again performed to characterize the asymmetries.

- For more severe deformities, consideration must be given to a complete revision of the primary cleft lip and nose repair.^{3,4}

Positioning

- Supine
- We typically use an oral RAE endotracheal tube. This minimizes any asymmetry caused by taping a standard endotracheal tube in the corner of the mouth.
- The table is turned according to surgeon preference.
- The face is prepped with Betadine, and sterile drapes are applied. A head wrap or four towels may be used for draping according to surgeon preference.

Approach

- Markings: Mark all the key anatomical landmarks of the lip and nose (eg, alar bases, columella, peak and nadir of Cupid's bow, white roll, and wet-dry junction). Tattoo the key points with methylene blue.
- Measure: Measure both the normal and cleft sides with calipers to determine the exact discrepancy of height and/or width in the lip and nose that requires correction.
- Epinephrine: Consider whether epinephrine is needed for your surgery. The hemostatic benefit is helpful in many cases. However, for subtle contour abnormalities, epinephrine infiltration may obscure your ability to assess the result on the table. In these cases, pinch the lip between the thumb and index finger to occlude the labial artery while you are incising the tissues and use Bovie electrocautery sparingly.
- Skin repair: Although hypertrophic scarring may be inherent to the patient, all precautions are taken to minimize this risk. Care is taken to ensure a tension-free closure. The skin is approximated with 5-0 or 6-0 Monocryl buried dermal sutures. When these are placed precisely, additional cutaneous sutures may not be required. When cutaneous sutures are needed, we use strategically placed 6-0 fast-absorbing plain gut or 6-0 nylon sutures in the epidermis to align the skin edge. These are removed 4 to 5 days after surgery.
- Muscle repair: Muscular dehiscence may be suspected in patients who have a muscle bulge laterally with facial animation. In addition, muscular dehiscence can contribute to a shortened lip, notching of the mucosa, or widening of the cutaneous scar. When these are noted, reconstruction of the orbicularis oris musculature must also be performed with the repair. The orbicularis oris

muscle is dissected free from the skin and mucosa. When the muscle is found dehiscenced, it is reapproximated or overlapped. Some surgeons describe a benefit to tightening the orbicularis oris muscle with horizontal mattress sutures to evert the muscle and accentuate the philtral column.

- Mucosa repair: After the planned local tissue rearrangement or excision, the mucosa is typically repaired with 5-0 chromic gut sutures. These can be placed as everting horizontal mattress sutures to prevent a notch in the vermilion and mucosa.

TECHNIQUES

■ Deformities of Cupid's Bow

Small Vermilion Mismatch (Less Than 1 mm) or a Widened Scar at the Cutaneous-Vermilion Border

- This can be managed by a diamond or curved excision of the scar, similar to the classically described Rose-Thompson straight line repair (**TECH FIG 1A**).
- The Cupid's bow nadir and high points are marked (**TECH FIG 1B**). An equal distance from high point to nadir is transposed to the cleft side, and this is typically positioned on the medial side of the scar. The vermilion border is marked medially and laterally to the scar that is to be excised. These points will come together to create the new high point of Cupid's bow on the cleft side.
- The white roll is marked, as is the red line wet-dry junction. The diamond excision is marked to excise the scar or mismatch and allow realignment of the vermilion border and white roll.
- The critical points are tattooed with methylene blue.
- Epinephrine-containing solution is infiltrated into the tissues for hemostasis.
- Using an ophthalmic knife, the diamond is excised through the skin down to muscle. If the muscle repair is adequate, superficial scar is excised, but the muscle is left intact.

TECH FIG 1 • A. Hypertrophic scar at the vermilion border with slight shortening of Cupid's bow on the cleft side preoperatively. The remainder of the cutaneous scar is well healed. **B.** The peak and nadir of Cupid's bow are marked on the noncleft side and transposed to the cleft side. The white roll is marked and these points are tattooed. A diamond excision of the scar is marked at the vermilion border. **C.** The diamond excision realigns the vermilion border and white roll and provides adequate additional length to balance Cupid's bow.

- 5-0 Monocryl is used to realign the vermilion border with a deep dermal suture (**TECH FIG 1C**). Additional deep dermal sutures are used to realign the wound margins precisely.
- 5-0 Chromic is used to reapproximate the mucosa with everting sutures. To prevent a standing cone or “dog ear,” excess mucosa is excised as needed in this process.

Cupid's Bow Mismatch of 1 to 2 mm

- For a Cupid's bow mismatch of 1 to 2 mm (**TECH FIG 2A**), a small triangular flap is inserted at the cutaneous border.
- This excision and reconstruction are often similar to the microform cleft repair described by Mulliken.⁴
- The cutaneous-vermilion border, white roll, Cupid's bow peak on the normal side, low point, and peak on the cleft side are marked and tattooed (**TECH FIG 2B**).
- Using calipers, the distance from subnasale to the normal Cupid's bow peak is measured, and the equal distance from subnasale is marked on the cleft side.
- A laterally based cutaneous equilateral triangular flap is marked on the lip above the white roll, with the base of this triangle being the difference in the distance between subnasale and height of Cupid's bow peak on each side.
- An incision of equal length is marked on the medial lip element above the white roll.

- The length of vertical excision is long enough to excise any abnormal scar tissue or to prevent formation of a “dog ear.”
- If there is a deficiency of central tubercle vermillion, a laterally based triangle of vermillion may be designed as well.³ If there is an excess of lateral mucosa, a mucosal excision may be included (**TECH FIG 2C**).
- The tissue is infiltrated with epinephrine. It is excised with an ophthalmic knife or no. 15 blade.
- The scar tissue is excised and the skin flaps are separated from the underlying orbicularis oris muscle.
- The muscle is reconstructed if needed, and skin and mucosa repair proceeds as previously described (**TECH FIG 2D,E**).

TECH FIG 2 • A. Lip deformity characterized by both shortening of Cupid's bow on the cleft side and lateral mucosal fullness. **B.** The peak and nadir of Cupid's bow are marked on the noncleft side, and the peak of Cupid's bow is marked symmetrically on the cleft side. The excision is designed with a laterally based triangular flap at the white roll. In addition, the lateral mucosal fullness is addressed with an excision planned along the red line or junction of wet and dry mucosa. **C.** After excision of the tissues, prior to repair. Mucosa is being excised in both the transverse and vertical planes. **D.** Closure includes the inset of a

laterally based triangular flap above the white roll to increase the length of the lip on the cleft side. This realigns and balances Cupid's bow. **E.** After excision of excess mucosa, the mucosa is more symmetric. The scar is hidden along the red line and closed with 5-0 chromic sutures.

Cupid's Bow Asymmetry More Than 2 mm High

- For a larger asymmetry, a complete revision of the cutaneous scar is performed (**TECH FIG 3**).
- Many primary lip repair techniques may be adapted to achieve the necessary goals in these more complex deformities.
- The vermilion discrepancy may be addressed by rerotation of the medial lip element as in a classic Millard repair (**TECH FIG 3C**).
- Use of a triangular flap above the white roll in the manner first described by Tennison and Randall and subsequently modified by Fisher⁵ is also an option for a complete revision of the lip repair to address a major deformity.
- The orbicularis oris muscle may need to be reconstructed fully or in part to achieve adequate repair.
- In the bilateral cleft lip, complete revision is used for patients with a wide philtrum, significant philtral scarring, or a severe deficiency of vermilion in the midline (**TECH FIG 4**).

TECH FIG 3 • **A.** Shortening of the unilateral lip with mild widening of the cutaneous scar. **B.** A complete excision of the cutaneous scar is planned. A backcut is designed to allow secondary rotation of the medial lip element. **C.** After rotation of the medial lip element, Cupid's bow is now more symmetric. **D.** The improvement in the symmetry of Cupid's bow is maintained at 18 months postoperatively.

TECH FIG 4 • A,B. A 12-year-old boy with significant residual cleft lip and nasal deformity after bilateral lip repair. Cupid's bow is unbalanced, and there is a paucity of mucosa in the central tubercle. He has had no correction of his cleft nasal deformity with lateral displacement of the alar bases. **C.** With this degree of deformity, a complete bilateral lip and nose repair is planned and marked as if this were a primary incomplete bilateral lip repair. The peak of Cupid's bow is marked at Noordhoff point on the lateral lip element. The skin and mucosa between this and his existing scar are planned for excision. **D,E.** The bilateral lip and nose are completely reconstructed to restore balance to Cupid's bow and the vermilion. Note the improved positioning and symmetry of the lower lateral cartilages and alar bases after open reconstruction with inverted-U rim incisions to address the lower lateral cartilages.

■ Abnormalities of the Vermilion and Mucosa

- Minor notches in the vermilion, asymmetries of the mucosa, incongruity of the red line, or asymmetry of the dry vermilion may all be managed with small elliptical excisions or local tissue rearrangement.
- Incisions are confined to the mucosa and vermilion unless a cutaneous deformity must also be addressed.
- Each problem discussed here has a slightly different solution, but our typical step-by-step approach is as follows:
 - Assess the deformity and design the excision or flap for reconstruction.
 - Mark the red line for accurate realignment later. Tattoo this with methylene blue if needed.
 - We typically do not infiltrate the tissues with epinephrine-containing solution when addressing a mucosal defect. The infiltration will distort the tissues and prevent accurate intraoperative assessment. We find it is easier to determine if adequate tissue has been excised or rearranged without infiltration.
 - Rather than using epinephrine, the labial artery is pinched between two fingers while making an incision in the tissues with a no. 15 blade.
 - Electrocautery is used for hemostasis as needed.
 - Mucosal flaps are elevated from the underlying orbicularis oris muscle.
 - The orbicularis oris muscle is reconstructed as needed with 4-0 Monocryl mattress sutures.
 - The mucosa is redraped to assess contour of the lip. Additional excision, augmentation, or dissection is performed as needed to optimize the contour.
 - Closure of the mucosa is performed with interrupted 5-0 chromic sutures.

Malalignment of the Red Line

- This may lead to a notch in the border or an area of chapped mucosa interposed between dry vermilion.
- A notch caused by inadequate dry vermilion at the central tubercle can be addressed by advancing lateral vermilion excess. A small laterally based triangular flap of vermilion is raised above the muscle. An incision is made along the red line medially. After any necessary muscle repair, the lateral triangular flap is inset into the medial incision.
- Alternatively, when wet mucosa is interposed in the vermilion, this may be excised with a vertical ellipse of this tissue. The mucosa is elevated on both sides to reduce tension. After muscle reconstruction or reinforcement, the

mucosa is closed with the red line now in precise alignment.

Lateral Mucosa Fullness

- This is common after unilateral cleft lip repair. It can often be corrected by excising an ellipse of tissue from the mucosa.
- A transversely oriented ellipse addresses excess in the anteroposterior direction. This may be placed along the red line if there is an excess of both dry vermilion and mucosa (**TECH FIG 5**), or it may be hidden in the labial buccal sulcus if the excess is composed only of wet mucosa.
- Festooning of the lip suggests excess mucosa in the transverse direction. This should be addressed with a vertical ellipse of mucosa along the cleft scar.
- We find that often both ellipses are needed (**TECH FIG 6**). In these cases, both are marked and the closure is usually in the shape of a “T.”

TECH FIG 5 • **A.** Lateral mucosal fullness is noted after unilateral cleft lip repair. **B.** The excess was primarily in the anteroposterior dimension. A transverse ellipse, centered on the red line, is marked for excision to address the region of excess. **C.** After

excision and closure, the contour of the lip margin is improved.

TECH FIG 6 • A. This child has lateral mucosa excess at rest and **(B)** with animation after unilateral cleft lip repair. **C.** On closer evaluation, the mucosal excess was felt to be in both the transverse direction and anteroposterior direction. For this reason, both a transverse ellipse and vertical ellipse were marked. The final closure will be in a “T” configuration along the cleft lip scar and in the buccal sulcus.

TECH FIG 7 • After fat is harvested from the lower abdomen, it is placed in 1-mL syringes for injection. This is typically injected via a fine fat grafting cannula or 18-gauge needle under the vermilion border.

Hypoplastic Medial or Lateral Lip Element

- In this case, soft tissue augmentation is required. Autograft, allograft, and synthetic tissue fillers have all been described. When possible, our preference is to use autograft either as a structural fat graft or dermal fat graft.
- Structural fat grafting may be used for secondary lip augmentation.
 - Autologous fat is harvested in the standard fashion from the lower abdomen and prepared according to the Coleman technique.
 - This can then be injected under the vermilion border using a very small cannula (**TECH FIG 7**).
 - Structural fat grafting is versatile. In addition to augmenting the vermilion, it may also be used to augment a deficient philtral column or nostril base.⁶ Limitations with fat grafting include unpredictable resorption and survival, as well as the risk of asymmetric hypertrophy with added weight gain over time.
- Autologous dermal fat graft is used when a larger augmentation is needed (**TECH FIG 8**).
 - The requisite size graft is typically harvested from the groin and de-epithelialized.

- The graft is ideally positioned between the mucosa and muscle under the vermilion border and dry vermilion.
- Two small counterincisions in the mucosa can be made to create a tunnel for the graft, which is passed with a tendon passer (**TECH FIG 8D**). Chromic sutures are placed on both ends of the graft prior to passing it through the tunnel. These are then used to anchor the graft into the appropriate location.
- If a Z-plasty or V-Y advancement of the buccal sulcus tissue is planned in addition to augmentation, this flap is raised and the dermal fat graft may be placed directly and sutured into place (**TECH FIG 9**). We commonly use this strategy to augment the central tubercle in the bilateral cleft lip.

TECH FIG 8 • A. After unilateral cleft lip repair, this patient has an asymmetric free margin of the lip. She has mucosal excess on the left, with a relatively hypoplastic lip on the right side. Given the thin lip on the right side, augmentation with an autologous dermal fat graft was planned. **B.** Harvest from the right hip was planned, with the incision in a favorable location. **C.** The graft is de-epithelialized and thinned to the necessary size. **D.** In this case, a tunnel was made from the lateral commissure to the central lip. A tendon passer is used to introduce the graft into the planned location along the right lip. **E.** After graft inset, the lip thickness is more uniform across the upper lip.

- Dermal allograft is an alternative to autologous tissue and may be used in a similar manner to a dermal fat graft.⁷

Notch in the Free Edge of the Lip or Whistle Deformity

- This may be caused by inadequate tissue, dehiscence of the orbicularis oris muscle, or scarring of the mucosa that leads to tethering or shortening of the lip.
- When scarring is present, the buccal mucosa may be lengthened by local tissue rearrangements or grafts, such as:
 - Mucosa Z-plasty
 - V-to-Y advancement of the buccal sulcus tissue

- Transposition of a buccal mucosa flap⁸
- Interposition of a buccal mucosal graft harvested from inside the lateral cheek
- When the cause is a deficiency of tissue rather than scarring, augmentation with autologous fat may be adequate.
 - For a mild deficiency, structural fat grafting may be used.
 - Elevation of a buccal flap and augmentation with dermal fat graft are used for a moderate-size defect (see **TECH FIG 9**).

TECH FIG 9 • **A.** Persistent central vermilion deficiency after bilateral cleft lip repair. **B.** In the area of notching, an anteriorly based mucosa flap is designed. The flap and surrounding mucosa are elevated from the orbicularis muscle, and a dermal fat graft is positioned in the region of deficiency. **C,D.** After augmentation with a dermal fat graft, the fullness of the central tubercle fullness is improved.

- In more significant cases, or when vermilion deficiency is associated with a widened philtrum and nasal base, complete revision of the repair may be

performed to recruit additional lateral mucosa into the defect (see **TECH FIG 4**).

- In severe cases, usually after bilateral cleft lip repair, the whistle deformity may require reconstruction with an Abbe flap (see below).
- The orbicularis oris muscle must be reconstructed in all cases.

■ Abbe Flap

- The bilateral cleft lip often is accompanied by a deficiency of mucosa as well as a shortened philtrum. Furthermore, horizontal lip deficiency may limit the ability to reconstruct the central tubercle by borrowing tissue from the lateral lip elements.
- For these severe whistle deformities (**TECH FIG 10A**), an Abbe flap may provide the best option for reconstruction of the entire philtral unit.^{9,10}
- The patient is nasally intubated in preparation for surgery (**TECH FIG 10B**).
- If the patient is in braces, tight elastics are placed to prevent full mouth opening after surgery. Alternatively, intermaxillary fixation screws may be placed with tight elastics or wires.
- The flap is designed in the midline of the lower lip (**TECH FIG 10C**). The length and width of the new philtrum are designed and drawn onto the lower lip. The flap tapers slightly toward midline as it approaches the labiomental crease. Darts are made at the labiomental crease to address the donor site “dog ear” at closure.
- The vermilion border and white roll are marked and tattooed on the lower lip.
- The flap is incised full-thickness through the skin, muscle, and mucosa on one side (**TECH FIG 10D**). During this dissection, the location of the labial artery is noted, so that this area is well preserved on the contralateral side. A Doppler may be used to confirm the pedicle location if there is prior scarring in the area.
- The remainder of the flap is dissected with preservation of the labial artery. A small muscular cuff is preserved around the artery. The composite flap is then able to be rotated a full 180 degrees.
- The lower lip incision is closed in layers. The mucosa is repaired with 4-0 chromic gut, the lower lip orbicularis oris muscle is repaired with 3-0

Monocryl sutures, and the skin is closed with 5-0 Monocryl sutures in the dermis and 6-0 nylon in the skin.

- The critical points of the upper lip are marked. The columella, vermilion border, and white roll are marked and tattooed. The scarred prolabium is marked for excision.

TECH FIG 10 • A. Bilateral cleft lip with significant whistle deformity composed of deficiency of mucosa, vermilion, and philtrum. On worm's-eye view, the patient also has a severely shortened columella. **B.** Preparation for Abbe flap includes nasal intubation. This patient's braces were used for intermaxillary fixation with heavy elastics. **C.** The Abbe flap is planned and marked in the midline of the lower lip. The flap is measured to the desired length and width of the new philtrum. The length is limited by the

location of the labiomental crease, but this crease is used to accommodate any dog ear at closure. The columella, scarred philtrum, and new high points of Cupid's bow are marked. The high points of Cupid's bow are marked to match the length and fullness of the lower lip flap. **D.** The central upper lip defect is created and the orbicularis oris muscle is dissected out for repair. The lower lip Abbe flap is cut full thickness through skin, muscle, and mucosa. One side remains pedicled on the labial artery. **E,F.** The Abbe flap is able to be rotated a full 180 degrees into the upper lip defect. **G.** The Abbe flap is inset with care taken to align Cupid's bow and the lower lip vermilion border. **H.** After 10 to 14 days, the flap is well healed and ready for division. The lip pedicle may be compressed to ensure there has been adequate vascular ingrowth. **I.** The mucosal bridge is divided, and the mucosa is repaired. Silicone tape is applied to the cutaneous portions of the scars to optimize healing. **J.** Several months after surgery, the patient has improved lip contour and increased philtral length.

- The new high point of Cupid's bow is selected. This is ideally at a height that matches the new philtral column created by the Abbe flap. Furthermore, this point is selected such that the thickness of the upper lip mucosa matches the lower lip tissue bulk to achieve a smooth mucosal contour.
- Prior to incising the upper lip, 0.25% bupivacaine is infiltrated as bilateral infraorbital nerve blocks. Epinephrine may be infiltrated into the upper lip tissues.
- The cutaneous incisions are made with a no. 15 blade, and the prolabial scarring is excised. The upper lip is divided at 90 degrees to the white roll and vermilion. The orbicularis oris muscle is dissected and preserved.
- Buccal mucosal incisions are made bilaterally to advance the lateral lip medially toward the new philtrum. The lateral lip is advanced and the buccal

mucosa backcut is closed with 4-0 chromic gut suture.

- After the defect has been created, the Abbe flap is rotated to fill the defect (**TECH FIG 10E,F**). The mucosa is inset with 4-0 chromic gut to the lateral lip elements.
- The orbicularis oris muscle of the upper lip is then repaired to the muscle of the Abbe flap.
- The vermilion and white roll are aligned at the previously tattooed points, and the remainder of the skin and mucosa is inset (**TECH FIG 10G**).
- During the inset, the color of the Abbe flap is monitored to ensure the flap remains adequately perfused. If perfusion is compromised, routine maneuvers for flap ischemia are taken, such as release of tension, replacement of flap to donor site, hyperbaric oxygen, etc.
- Flap division is performed 10 to 14 days later (**TECH FIG 10H-J**). After division, the mucosa of the upper and lower lip is closed with 5-0 chromic gut sutures.
- The vermilion Abbe flap may be modified from this pattern to address a severe defect of the mucosa only (**TECH FIG 11**). This eliminates the need for cutaneous scarring while augmenting a severe deficiency of tissue at the central tubercle.

TECH FIG 11 • A. In some cases, the philtral length is adequate, but the deficiency of vermilion is so severe that Abbe flap is considered. **B.** In this case, however, the Abbe flap is designed to stay within the mucosa and does not cross the vermilion on either the upper or lower lip. **C.** Two weeks later, the flap is ready for division. **D.** After several months, the mucosa is well healed with a significant improvement in upper lip contour.

■ Lip Pits

- Lip pits are commonly associated with cleft lip and palate in van der Woude syndrome. Most lip pits occur on the lower lip as paired structures lateral to midline; however, midline pits on the upper or lower lip are also possible. They can range from slight depressions to deep tracts lined with epithelium.¹¹
- The tracts are associated with serous or mucous glands along their course and track toward the labiogingival sulcus.
- Excision must include management of the mucosal deformity as well as removal of the entirety of the tract.
- The orbicularis oris muscle may need to be reconstructed after excision of the tract.
- A lacrimal probe is used to assess the course and depth of the tract. Methylene blue is then injected into the tract with an angiocatheter to mark the tract.
- The mucosal excision is planned to optimize contour. Authors have described multiple different approaches to address the concerns with mucosal contour.

Simple Transverse Elliptical Excision of the Pit and Tract

- In this technique, a transverse ellipse is designed around each pit (**TECH FIG 12A,B**).
- Dissection is carried down around the tract until it is completely excised, using the lacrimal probe to guide the excision.
- The orbicularis oris muscle is reconstructed with 4-0 Vicryl sutures.

- The mucosa is closed using interrupted 5-0 chromic gut sutures (**TECH FIG 12C**).
- Simple excision may be adequate when a single lip pit is present or when lip pits are small and shallow.
 - Multiple deep pits may result in contour abnormalities of the lower lip.

Vertical Elliptical Wedge Excision

- A full-thickness vertical elliptical wedge of the lower lip is designed. This wedge extends to the mucosa internally and crosses the vermilion border onto the skin externally (**TECH FIG 13**).
- The lacrimal probe is used to verify that the sinus tract is contained within the wedge. The wedge is excised full thickness.
- The orbicularis oris muscle is repaired.
- The mucosa, vermilion border, and skin are closed.
- Though this technique may lead to a smoother contour of the lower lip, the scarring on the skin of the lower lip is a major drawback.

TECH FIG 12 • **A.** Central lower lip pit in a child with van der Woude syndrome. **B.** Simple transverse elliptical excision. **C.** After simple transverse elliptical excision of the lip pit.

Split Lip Advancement Technique (SLAT)¹²

- In SLAT, the pits and tracts are excised in a central wedge of tissue from the vermilion border to the gingivobuccal sulcus.
- The lip is then split from the central incision to a point near the commissure.
- An incision is made along the vermilion border through the pars marginalis. This incision is then carried vertically and inferiorly in a plane between the orbicularis oris muscle and the submucosa (**TECH FIG 14**).
 - The labial artery is preserved within this posterior mucosa flap with the pars marginalis, whereas the skin and majority of the orbicularis oris muscle are maintained in the anterior flap.
- The posterior mucosa flap is advanced toward the midline, and the orbicularis oris muscle is reconstructed.
- Skin and mucosa closure is in a T from the midline along the vermilion border anteriorly.

Inverted-T Excision¹³

- The lip pits are both included in a large transverse ellipse. The outer edge of this ellipse is parallel to the white roll, which helps to maintain a constant thickness of vermilion.

TECH FIG 13 • Vertical wedge excision of lower lip pits.

TECH FIG 14 • SLAT technique for lower lip pits.

TECH FIG 15 • Inverted-T excision of lower lip pits.

- Centrally, the ellipse meets a vertical inferior wedge that extends from the lip pits laterally toward the midline of the lower labiobuccal sulcus (**TECH FIG 15**).
- Using the lacrimal probe to identify the sinus tracts, these are fully excised within the vertical wedge of tissue.
- The vertical wedge is excised, and the orbicularis oris muscle is reconstructed.
- The transverse wedge is closed with chromic gut sutures.

TECH FIG 16 • V-Y mucosal flap with use of dermal allograft for augmentation.

Excision and Reconstruction of Lower Lip Fullness With Acellular Dermal Allograft¹⁴

- A large central V-shaped mucosal flap is designed with the apex in the midline of the inferior gingivobuccal sulcus. The lateral arms of the flap include ellipses that excise the lip pits.
- The pits and tracts are fully excised, and the orbicularis oris muscle is reconstructed.
- To restore fullness to the lower lip, an acellular dermal allograft, structural fat grafting, or autogenous dermal fat grafts are utilized to create a natural shape for augmentation (**TECH FIG 16**).
 - This is placed under the V-shaped mucosal flap and sutured into place with 4-0 Vicryl sutures at each commissure.
- The mucosa is closed as a V-to-Y advancement flap with chromic sutures.

PEARLS AND PITFALLS

Etiology of deformities

- Some secondary cleft lip deformities are intrinsic to the disease.
- Others are iatrogenic from the primary repair. Care must be taken to create a balanced lip and nose with release and repositioning of the lower lateral cartilage on the cleft side and complete reconstruction of

	the orbicularis oris muscle sling at the <i>first</i> operation to minimize the risk of iatrogenic deformities.
Analysis	■ Accuracy in analyzing the problem is essential. One must identify the underlying anatomic cause of the deformity in order to accurately reconstruct it. ■ Assess the entire lip/nose complex in planning your reconstruction. ■ Assessment must include all tissues from the underlying bony skeleton, mucosa, muscle, skin, cartilage, and soft tissue.
The repair must match the deformity.	■ Minor deformities may be addressed with minor scar revisions and insertion of triangular flaps. ■ A more complex deformity involving multiple elements is best treated by a complete revision of the lip and nose repair.
Mucosa excess	■ This may often be resolved by direct excision.
Mucosa deficiency	■ A minor deficiency of the central tubercle may be addressed by creation of a laterally based vermilion triangular flap, which can be inset in the central tubercle medially. ■ A larger deficiency of lip soft tissue can be treated by various techniques including autologous structural fat grafting, autologous dermal fat graft, or allograft.
Abbe flap	■ An Abbe flap is best used to reconstruct a deficiency of all tissues of the central lip unit—philtral skin, vermilion, muscle, and mucosa. ■ This treats the most severe forms of lip notching that cannot be addressed adequately by local flaps and augmentation alone.
Lip pits	■ The entire pit and epithelialized tract must be excised. ■ Reconstruction requires repair of the orbicularis oris muscle and reconstruction of the mucosa to achieve a natural lower lip contour.

POSTOPERATIVE CARE

- Antibiotic ointment is typically applied to the incision until it is healed.
- Patients often may resume their usual diet.
- With young children, elbow restraints may be used to keep the child from putting the hands in the mouth or traumatizing the incision.
- Special care is taken to optimize cutaneous scar healing after surgery.
 - When cutaneous absorbable sutures are used, we ensure that they have absorbed by 4 to 5 days postoperatively. We apply diluted hydrogen peroxide to them several times daily to speed this process along to avoid track marks

from the sutures.

- Permanent sutures are removed within 5 days after surgery to avoid scarring.
- Once the wound margins have healed, silicone tape is applied to the scar. It is changed every few days and used continuously for approximately 3 months.
- Patients and families are educated on techniques in scar massage and avoidance of sun exposure for the first year after surgery.
- If hypertrophy is noted in the early postoperative period, consideration is given to applying steroid-impregnated tape or performing steroid injections with triamcinolone.

OUTCOMES

- Outcomes after correction of secondary deformity are usually good.
- Depending on the severity of the deformity, asymmetry or contour abnormalities can be persistent.
- The degree of residual deformity and patient level of concern typically dictate whether additional revision surgeries are recommended.

COMPLICATIONS

- Inadequate correction of the deformity may be caused by an incorrect diagnosis and treatment plan, such as performing a minimal excision when a complete revision is necessary.
- Hypertrophic scarring is possible, and attempts are made to minimize it as described.
- Wound dehiscence and infection are rare.
- Intraoperative complications such as bleeding or anesthesia concerns are rare.

7 Delayed Hard Palate Repair in UCLP Patients

CHAPTER

Jan Lilja

DEFINITION

- In UCLP patients, the cleft palate will lead to speech difficulties.
- Poor ventilation of the Eustachian tubes results in a high incidence of hearing problems due to middle ear infection.
- Early surgery on the palate may result in reduced maxillary growth.
- Late surgery on the palate may result in aberrant speech.

ANATOMY

- The palate can be thought of as an anterior bony part limited by the dental arch and a posterior mobile part where muscles, oral mucosa, and nasal mucosa are important functional structures.
- The anterior palate (hard palate) is a horseshoe-formed bony structure concave toward the mouth and convex toward the nose where it forms the nasal floor. Both sides are covered by mucosal epithelium.
- The muscles in the posterior part (soft palate) will act on the soft palate and produce tension, lifting, or lowering of the soft palate. Lifting of the soft palate is most important and is accomplished by the levator veli palatini muscles. In speech, the soft palate should be lifted as far back as the posterior pharyngeal wall and be able to stop airflow through the nose in order to produce distinct pronunciation of certain sounds.

PATHOGENESIS

- In a complete cleft of a unilateral cleft lip and palate, a cleft separates the lip, the alveolar bone, and the hard and soft palate. The lateral incisor on the cleft side is usually missing in both deciduous and permanent dentition. The cleft

separates the hard palate lateral to the vomer, establishing a cleft side and a noncleft side in the hard palate where the vomer is attached to the noncleft side. The soft palate is separated in the midline, but the cleft side is usually smaller.

- Feeding is often difficult for the child because there is an opening between the oral and nasal cavity. Food may pass into the nasal cavity and sucking is compromised because adequate negative pressure cannot be achieved during breast-feeding.
- In the soft palate, the muscles are not attached to each other; the muscles follow an anteroposterior direction along the cleft edges. Some of the muscles are attached to the posterior edge of the hard palate on both sides of the cleft.
- This morphological aberration impairs development of speech and hinders ventilation of the Eustachian tube.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The diagnosis of a patient with complete unilateral cleft lip and palate is usually made by clinical examination.
- Photographs taken from anterior, lateral, and inferior views can be taken to document the condition.
- In some centers, plaster casts are made from both upper and lower jaws.
- Postoperatively, the patients are followed on a regular basis with photos, speech evaluation, cephalometric assessment, and plaster casts.
- When needed for evaluation of velopharyngeal incompetence (VPI), nasendoscopy and videofluoroscopy can be used.

SURGICAL MANAGEMENT

- There are numerous protocols for operating on the palatal cleft in patients with complete cleft lip and palate. These protocols differ in procedure and timing.
 - Early surgery of the soft palate is a prerequisite for good speech, but combined with closure of the hard palate, it will produce reduction of maxillary growth.
 - Closure of the whole palate at an older age will give less problems with maxillary growth but may give more problems with impaired speech.
- When delayed hard palate repair is performed in UCLP patients, soft palate closure is performed early to promote speech, and hard palate closure is delayed until 2 years of age to promote growth. The palatal closure is continued over to the oral side, where a pushback procedure can be done within the soft palate.

- Closure of the soft palate with a posteriorly based vomer flap will result in anchorage of the anterior part of the soft palate to the base of the vomer flap.
- This part of vomer is situated at the insertion of the vomer to the cranial base. The direction of the soft palate will therefore be posterior-upward, resulting in reduction of the openings toward the nose.
- This may explain the favorable speech results in our patients, improving the posterior positioning of the levator muscles and thereby reducing VPI.

Positioning

- The patient is positioned supine on the operating table.
- A shoulder roll is placed, serving to tilt the head backward to facilitate visualization.

TECHNIQUES

■ Soft Palate Repair

- Incisions begin around the posterior part of the maxillary tuberosities and then follow a zigzag route at the posterior border of the hard palate (**TECH FIG 1A**).
- A posteriorly based vomer flap is dissected, which does not reach the vomero-premaxillary suture anteriorly. The base of the flap lies at the junction of the vomer with the cranial base (**TECH FIG 1B**).
- Mucosal flaps in the soft palate are raised by blunt dissection. The hamulus is identified but not broken (**TECH FIG 1C**).
- The insertions of the velar muscles and the nasal mucosa at the posterior border of the hard palate are cut (**TECH FIG 1D**).
- A flap with the muscles attached to the nasal layer is then dissected free and mobilized.
- The palatal muscles, including the levators, are then reconstructed to a transverse course at the level of the opening of the Eustachian tube (**TECH FIG 1E**).
- The vomer flap is raised, and the nasal layer of velum can be closed anteriorly to the level of the muscular sling by use of the vomer flap. In this way, the vomer bone is connected to the anterior velum (**TECH FIG 1E**).

TECH FIG 1 • Soft palate closure. **A.** The incisions follow a zigzag line between the soft and hard palate. A posterior vomer flap is dissected, which has its base at the posterior-cranial part of the vomer. **B.** Both sides of velum are divided into two layers: the oral mucosa and the nasal mucosa. **C.** The muscles including the nasal mucosa are cut at the border of the hard palate. **D.** The muscles are redirected to a transverse course, sutured together medially in a posterior position, and also attached anteriorly to the backward-turned vomer flap. **E.** The muscles and the raw surface of the vomer flap are covered by the oral flaps, which are pushed in a medial-posterior direction.

■ Hard Palate Repair

- Incision lines are made for a flap on the noncleft side using palatal mucoperiosteum. The flap is based on the vomer (vomer flap). On the cleft side, an incision is made at the cleft border (**TECH FIG 2A**).
- The vomer flap is raised leaving a raw bone surface on the noncleft side (**TECH FIG 2B**).
- Suturing starts on the oral mucosa, going into the pocket between the bone and the mucoperiosteum. The needle catches the vomer flap from the mucosal side, coming out on the raw side, going back to the mucosal side and thereafter into the pocket and out on the mucosal side. Therefore, the knots are tied on the mucosal side (**TECH FIG 2C**).

TECH FIG 2 • Repair of a residual cleft in the hard palate. **A.** Incision lines. On the noncleft side, the incision goes into the flat medial part of the palate. On the cleft side, the incision is made at the cleft border between the oral and nasal mucosa. **B.** The vomer flap is raised. It contains some oral mucosa leaving a raw bone surface in the medial part of the palate on

the noncleft side. Sutures are put to bring the vomer flap into the incision on the cleft side. **C.** The vomer flap is brought into the pocket between bone and mucoperiosteum on the cleft side. Suturing starts on the oral mucosa going into the pocket between the bone and the mucoperiosteum. The needle catches the vomer flap from the mucosal side, coming out on the raw side and then going back to the mucosal side and thereafter into the pocket and out in the mucosa. Pulling the suture will bring the vomer flap into the pocket between the bone and the mucoperiosteum. Four or five sutures are placed. **D.** The vomer flap sutured in place. **E.** The mucoperiosteum on the cleft side is sutured to the vomer flap in order to ensure good attachment.

- Four to five such sutures are placed.
- Pulling the suture will bring the vomer flap into the pocket between the bone and the mucoperiosteum (**TECH FIG 2D**).
- When the vomer flap is well positioned under the mucoperiosteum of the cleft side, sutures are tied, keeping the vomer flap in place and also covering the residual cleft with a one layer closure (**TECH FIG 2E**).
- Additional sutures are put at the border of the cleft, keeping the raw surface of the vomer flap attached to the raw surface of the mucoperiosteum on the cleft side, thereby ensuring good healing (**TECH FIG 2E**).

PEARLS AND PITFALLS

Diagnostic studies

- Nasendoscopy and videofluoroscopy are reserved postoperatively for cases demonstrating persistent VPI following palate repair.

Rationale for

- Delayed hard palate repair is done to optimize both speech and palatal growth.

delayed hard palate repair	■ Soft palate closure is performed early to promote speech. ■ Hard palate closure is delayed until 2 y of age to promote growth.
Posteriorly based vomer flap for soft palate closure	■ Base of the flap lies at the junction of the vomer with the cranial base and does not extend anteriorly to the vomeropalatine suture. ■ Results in anchorage of the anterior part of the soft palate to the base of the vomer flap ■ Improves the posterior positioning of the levator muscles and thereby reducing VPI
Soft palate repair	■ Insertions of the velar muscles and the nasal mucosa at the posterior border of the hard palate are cut. ■ The nasomuscular flaps are reconstructed to a transverse course at the level of the opening of the Eustachian tube. ■ The nasal layer of the nasomuscular flap is connected anteriorly to the vomer flap.
Hard palate repair	■ Closure is performed with a mucoperiosteal vomer flap raised from the noncleft side and sutured to the mucoperiosteum at medial edge of the cleft side. ■ Lateral mucoperiosteal dissection is avoided to minimize subsequent restriction of maxillary growth.
Outcomes	■ Long-term outcomes for both speech and growth have not been surpassed by any other surgical procedure for palate closure.

OUTCOMES

- Long-term growth and speech outcome are excellent in patients with two-stage palatoplasty with early soft palate repair and delayed hard palate repair.^{1,2}
- Results from growth studies and speech evaluation have not been surpassed by any other surgical procedure for palate closure.

CHAPTER Furlow Palatoplasty

T. Guy Thorburn

DEFINITION

- Furlow Palatoplasty is widely used technique for repair of either cleft palate (CP) or submucous cleft palate (SMCP). It can also be used in revision palate repair. Some surgeons who routinely use a Sommerlad repair for complete CP will instead use a Furlow for SMCP.
- The technique is based on the concept of lengthening the soft palate by use of “Double-opposing Z-plasties.” This involves mirror-image Z-plasties to the oral and nasal layers while also repositioning and reconstructing the levator muscle mechanism by keeping the levator palatini muscle on each side attached to the limb of the Z-plasty that moves posteriorly (**FIG 1**).¹
- Randall has described a variation for wider CP that involves using Langenbeck-type lateral releasing incisions to relieve the tension on the oral Z-plasty (**FIG 2**).²

ANATOMY

- The key functional issue in CP or SMCP is that the levator muscle mechanism is not in continuity on the two sides. In addition, the fibers become tethered to the posterior border of the hard palate. Successful functional palate repair therefore requires repair of the “levator sling” as well as just closure of the tissues across the cleft.
- The tethering to the hard palate seems to be an equal problem in differing types of cleft, whether unilateral or bilateral cleft lip and palate, cleft palate only, or SMCP.
- **Tip:** the oral layer of the soft palate is more elastic than the nasal layer, and the elasticity increases as you move from the hard palate–soft palate junction

toward the uvula. This means that the oral layer Z-plasty will tend to inset better with slightly wider flaps (closer to 80–90 degrees), whereas for the nasal layer, 60 degrees is sufficient. On the oral layer, the tissue elasticity is even greater in the posterior part of the palate, so the posterior limb is best designed slightly wider (around 90 degrees) as it will narrow after incision.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The initial assessment of the newborn with a cleft involving a palate would usually be alongside a pediatrician and will include:
 - Pregnancy and birth history (including information from any antenatal testing), gestation, birth weight, and Apgar scores.
 - Initial assessment of cleft type and any related anomalies, including any airway concerns suggesting Robin sequence.
 - Medical history, drug history, and allergy history.
 - Family history of clefts, other major health problems, or anesthetic problems and any genetic diagnosis.
 - Feeding history including bottle type (eg, squeezable bottle, free flow, Haberman, etc.), current weight, maximum percentage weight loss and number of days to regain birth weight, and volume/duration/frequency of feeds.
 - Physical examination to assess the upper airways, cleft type, cleft width, and how much deficiency there is of surrounding tissues, as well as any related anomalies or dysmorphic features. The pediatrician would then complete a fully newborn examination, looking in particular for related health issues such as cardiac, respiratory, renal, or neurological signs.

FIG 1 • Schematic diagrams of the Z-plasties of both

oral and nasal layers before and after inset.

FIG 2 • The variation described by Randall utilizing lateral releasing incisions (von Langenbeck) for wider or more complete cleft palate.

IMAGING

- No routine preoperative imaging is required for typical clefts. For older children presenting with SMCP or velopharyngeal incompetence (VPI), assessment with a speech lateral videofluoroscopy helps to assess the position of the levators and relative size of the soft palate to the size of the pharynx.
- Standardized preoperative clinical photos should be taken as these are invaluable when assessing outcomes many years later.

SURGICAL MANAGEMENT

Preoperative Planning

- A key aspect of successful cleft palate repair is in optimizing the patient prior to surgery. A pediatrician is a crucial member of the Cleft team. Although there is much discussion of age at palate repair, different team protocols vary from around 3 months old to 15 months or more. Very young babies will tend to be more susceptible to airway compromise around the time of surgery. Delaying repair until much older and speech has developed has been associated with poorer speech outcomes, particularly related to articulatory errors.
- **Tip:** our team protocol is for palate repair around 8 to 12 months (corrected for prematurity), but our emphasis is much more on ensuring the child is well

and thriving in the run-up to surgery. If they are not growing along their expected percentiles (with growth plotted on the appropriate chart for syndromic children), then we would want to address this before surgery. We will also routinely postpone for about 4 weeks if children have upper respiratory tract infections. By following this approach, we have seen a significant reduction in fistulae and concerns with speech function.

- Routine blood tests or cross match samples are not required, unless the child is known to have a specific risk factor.
- For children, with cardiac or respiratory problems, an up-to-date echocardiogram or sleep study may be relevant.

Positioning

- A south-facing Rae uncuffed or microcuffed tube is used. The taping of the tube needs to be secure but avoiding taping the mouth closed or limiting access. Taping in a V shape along the line of the mandible avoids displacing the tapes when the gag is opened.
- The child is placed supine on a warming blanket, with the head at the very end of the operating table. A large horseshoe gel head ring is placed under the shoulders and around the head to provide support without overextending the neck.

FIG 3 • Applying a sticker across the head drapes as a warning that the throat pack is in place, so that the drapes cannot be removed without first removing the sticker.

- A head drape is applied, and the face is prepped.
- **Tip:** we use a clear plastic drape [3M Steri-Drape Fluoroscope Drape 90 ×110 cm] over the trunk, which allows the anesthetist to see their endotracheal tube and circuit without disturbing the surgical field. We avoid any adhesive drapes near the endotracheal tube as these have the potential to catch and dislodge the airway.
- The table is tilted to a slight head-up position. An operating microscope is used for the procedure. The height of the table is adjusted once the microscope has been brought in to place (adjusted according to whether the surgeon prefers to sit or stand).
- A modified Dingman mouth gag is placed.
- A throat pack is placed, and a marker sticker put across the drapes as a reminder to ensure it is removed at the end. The sticker is placed so that the drapes cannot be removed without needing to disturb the warning sticker (**FIG 3**). The throat pack is also included in the scrub nurse count as an additional precaution.
- The nose and mouth are rinsed with aqueous chlorhexidine solution.

Approach

- The width of the cleft is measured, and any unusual features are noted.
- The incisions are marked with pen and ink. Depending on tissue condition and tension, the limbs of the oral Z are usually about 8 to 10 mm long. The angles are usually 80 to 90 degrees (slightly wider on the limb in the posterior soft palate) (**FIG 4**).
- **Tip:** for a right-handed surgeon, the oral layer Z is typically marked with the posteriorly based limb (where the muscle remains attached to the flap but has to be dissected from the nasal layer) on the left. This will tend to give the easiest access to the hardest part of the dissection.

FIG 4 • Oral layer markings for a standard Furlow palatoplasty. Note the angles of the Z are wider than for the skin, approaching 80 to 90 degrees.

TECHNIQUES

■ Hard Palate

- Levobupivacaine or bupivacaine long-acting local anesthetic with adrenaline 1:100 000 is infiltrated and left about 7 to 8 minutes for vasoconstriction (**TECH FIG 1A**). The injection is used to help hydrodissect the hard palate subperiosteal layer.
- **Tip:** Steri-Strips are placed to protect the corners of the mouth from abrasion by instruments (**TECH FIG 1B**).
- The incision is begun along the cleft margin (or in the midline for a SMCP or rerepair).
- For clefts involving the hard palate, incise carefully down to the bone along the margin of the hard palate and 3 to 5 mm past the hard palate–soft palate junction and elevate subperiosteally with a raspatory or Warwick-James elevator. Be careful approaching the posterior nasal spine as the tissues are more adherent here, and it is easy to tear the oral layer if there is a tethered salivary gland at this point. Switching between 15 blade and raspatory is usually necessary. **Tip:** for incising the margin of the rest of the soft palate and back to the uvula, a 12 blade tends to be easiest.
- Depending on the cleft type, it may be necessary to raise vomer flaps to help

close the nasal layer without tension.

- After raising the vomer flaps, elevate the nasal layer off the hard palate (again in a subperiosteal plane) with a raspatory or dental flat plastic.

TECH FIG 1 • A. Infiltration of local anesthetic with a Luer-lock syringe, using the infiltration to hydrodissect. **B.** Steri-Strip “cat’s whiskers” to protect the oral commissures during the procedure.

■ Oral layer

- A skin hook is placed on the left margin of the cleft, where the incision has been marked to create the posteriorly based flap. Using the skin hook to tension, a 15 blade is used to incise the oral layer and muscle, down to the nasal layer (which is left intact) (**TECH FIG 2A**).
- The muscle is then freed carefully from the nasal layer with the 15 blade and/or dissecting scissors. Keeping tension on the muscle toward the midline (rather than posteriorly or superiorly) makes this dissection easier without buttonholing the nasal layer.
- The muscle is freed off the nasal layer out toward the hamulus, so it is dissected more laterally than the extent of the oral layer incision.
- On the right side, the opposite flap is raised in a similar way but leaving the muscle intact on the nasal layer (**TECH FIG 2B,C**).
- **Tip:** after incising the leading edge of the posteriorly based oral flap and elevating the anteriorly based flap, then applying topical 1:1000 adrenaline on neuro patties provides excellent vasoconstriction and facilitates the

subsequent dissection (**TECH FIG 2D,E**).

TECH FIG 2 • A. Incising the oral layer posteriorly based flap (the muscle and mucosa flap on the left side of the palate). **B.** Raising the oral layer anteriorly based flap (the mucosa-only flap on the right side of the palate). **C.** Spread dissection with scissors can be very useful for identifying the plane between the muscle and the mucosal flap. **D,E.** After the initial dissection of the oral layer, topical 1:1000 adrenaline helps with the next stage of dissection by vasoconstricting. First, neurosurgical patties are placed in the wound to keep the solution in the desired area, and then 1 mL of 1:1000 adrenaline solution is dripped onto the patties.

■ Nasal layer

- To make access easier for the stage, a stay suture can be used to hold the oral flaps out of the way if the surgeon prefers, or the assistant can use a dental flat plastic or skin hook to do this (**TECH FIG 3A**).
- The nasal Z-plasty is a similar size to the oral layer. The angles are usually just over 60 degrees.
- On the nasal layer, the Z-plasty is a mirror image of the oral layer Z-plasty. At this stage, the muscle is present and attached to the nasal layer on the right side, while on the left, the nasal layer has already been dissected bare.
- A skin hook in the margin on the right side is used to place tension toward the midline. The posteriorly based flap is then raised by incising the nasal layer and muscle together with a 15 blade and/or dissecting scissors (**TECH FIG 3B**). The nasal layer is kept adherent to the muscle (**TECH FIG 3C**).
- **Tip:** when incising the muscle/nasal layer on the right, plan to keep a rim of the tensor aponeurosis tissue intact. This makes it much easier to inset the contralateral flap during closure.
- As with the muscle on the oral layer, it is necessary to free the muscle more laterally than the limit of the nasal layer incision.
- Once the posteriorly based flap is fully mobilized, hold it across to the opposite side to check the position of the nasal layer-only flap (**TECH FIG 3D**).

TECH FIG 3 • A. The longitudinal incision in the nasal layer. Note the effectiveness of the adrenaline, making

it much easier to see the correct planes. **B.** Incising the posteriorly based nasal layer flap (the muscle and mucosa flap on the right of the palate). Gentle traction of the muscle bulk toward the midline, as opposed to lifting or posteriorly, allows clean incision with either scissors or 15 blade. **C.** As the flap is incised and repositioned, the levator muscle (*marked*) comes into view on the nasal aspect of the other muscle fibers. **D.** Designing the flap in order to leave a rim of the tensor aponeurosis (*marked*) makes subsequent suturing of the flaps much easier. **E.** After checking the position with the right sided flap, the anteriorly based nasal layer flap is incised (the mucosa-only flap on the left side of the palate). **F.** Position of flaps at rest before inset. Assuming correct design of the flaps, they will tend to want to move toward their new positions, and the palate is already visibly lengthened.

- Then incise the anteriorly based nasal layer flap on the left side (**TECH FIG 3E, F**).

■ Closure

- Start with the inset of the nasal flaps—it is usually easier to begin by inseting the posteriorly based flap. A resorbable monofilament suture is used, preferably with a round or tapercut needle to avoid inadvertent tears of the mucosa. We use 5-0 Monocryl plus on the nasal layer and 4-0 Monocryl on the oral layer (**TECH FIG 4A,B**).
- **Option:** although this technique provides good overlap of the muscle mass on two sides, it is worth noting that the two levator muscles are not directly opposed or joined. Some surgeons therefore choose to directly suture the levators as well. In this situation, first complete inset of the nasal layer. Then a 5-0 nylon suture is placed through the levator muscle which is visible on the underside of the left oral layer flap. The oral flap is then held out to

length to allow placement of the suture to pick up the levator muscle on the right side (**TECH FIG 4C**). This muscle is lying out of direct sight on the deep aspect of the muscle that is attached to the nasal layer on the right side (**TECH FIG 4D**).

- The oral flaps are then inset. McGregor corner sutures combined with Barron sutures to the flap edges allow the avoidance of knots or ischemic areas at the distal ends of the oral mucosal flaps (**TECH FIG 4E**). If the oral flaps appear too tight, they can be inset a little short with a raw area left laterally.
- The local anesthetic is topped up.
- The throat pack is removed.

TECH FIG 4 • A. The nasal layer flaps are inset first; the rim of tensor aponeurosis makes suturing the nasal layer easier. **B.** The position of the nasal layer flaps after inset is complete. **C.** With inset of the nasal and oral layer posteriorly based flaps, the levator mechanism has been repositioned. But in the classic Furlow, the two levator muscles are not directly

connected, which can give an asymmetric lift of the palate. Therefore, some surgeons prefer to place permanent nylon mattress sutures directly connecting the two halves of levator. **D.** A schematic diagram of the soft palate in cross section to show the layers of the oral and nasal Z-plasties and the inset of the levator mechanism. **E.** The position of the oral layer flaps after inset is complete.

■ **Alternative: Z-Plasty with Intravelar Veloplasty**

- It is possible to use a hybrid of a Sommerlad and a Furlow approach. This can be particularly useful in SMCP.
- Preparation, draping, and hard palate are the same as above.
- The oral layer is raised as per a Sommerlad repair but is marked out a Z-plasty as for a Furlow repair.
- Incision and retraction of the Z-plasty flaps can give easier access for the muscle dissection (radical intravelar veloplasty) which is the same as for a Sommerlad repair.

TECH FIG 5 • The marking for the nasal layer Z-plasty at the base of the uvula in the hybrid procedure.

- The muscle is dissected off the nasal layer on both sides.
- A Z-plasty is then made in the posterior 1/3 of the nasal layer (in a mirror

image of the oral layer Z-plasty) (**TECH FIG 5**).

- **Tip:** a principle of Z-plasties is that increased length is achieved by redistributing tension in a lateral direction. Therefore, placement of the Z-plasty on the posterior 1/3 of the nasal layer, toward the base of the uvula, means that the lateral tightening achieved by the process of inseting the Z-plasty also tightens the velopharyngeal port.
- The muscles on the two sides are sutured with three 5-0 nylon mattress sutures, aiming to pick up both the levator muscle and the tougher tensor aponeurotic tissue with each bite. The knots must be tied very carefully to allow the ends to be cut extremely short.
- The oral layer is then closed with inset of the Z-plasty.

PEARLS AND PITFALLS

Timing of surgery

- Careful optimization of the baby prior to surgery is important; good growth following percentile lines is a useful indicator—a thriving baby at the time of surgery is more important than a specific age.

Shared airway

- As with all “shared airway” surgery, it is important for the anesthetist and surgeon to communicate well with each other—the WHO checklist and team brief are very useful for this.

Operating microscope

- The routine use of the operative microscope for palate repair gives excellent lighting and visualization of the operative field. It is also very helpful for giving trainees a better view and involvement, as well as reducing the strain on the surgeon’s neck.

Postoperative elevation

- Nursing the baby “head-up” in the recovery room and on the ward after surgery is helpful for reducing postoperative swelling—cuddling the baby over the parent’s shoulder tends to give ideal positioning.

POSTOPERATIVE CARE

- Topping up the local anesthesia with a long acting agent at the very end of the operation is useful for postoperative comfort and feeding.
- Nurse the baby with head elevated.
- Babies can be offered feeds straight away once they are awake.

- Monitor airway and saturations especially over the first night after surgery.

OUTCOMES

- The main outcome measures for cleft palate repair are fistula rate, structural speech problem rate, need for secondary surgery, and impact on maxillary growth.³
- There has been a systematic review comparing Furlow with straight-line repairs. This shows considerable variation in outcomes according to the cleft type. The average fistula rate ranged from 2.6% to 11.6% with different cleft types. The hypernasality rate (indicating structural speech problems) ranged from 8.9% to 18.5%, and the secondary surgery for speech rate ranged from 0% to 11.4%. There is a lack of data on the effect of maxillary growth from Furlow repairs, even though that was a starting focus in Furlow original description.⁴

COMPLICATIONS

- Infection, significant bleeding, and transfusion are all rare after palate surgery.
- Airway compromise is a potential risk especially in babies with Robin sequence and in younger/smaller babies.
- Fistula is reported to have a lower incidence than in some other techniques of palate repair in some series, but there is wide variation between series, and the extent and width of the cleft palate play a major factor in the fistula rate.
- Speech problems—whether VPI or “cleft type characteristic” articulatory errors.

9 von Langenbeck

Palatoplasty

CHAPTER

Kathryn V. Isaac and David K. Chong

DEFINITION

- Cleft palate is the failure of fusion of the palatal shelves during embryological development.
- There are many surgical techniques used for cleft palate repair. The repair technique chosen varies depending on the type of cleft palate and beliefs regarding facial growth and speech repercussions¹.

ANATOMY

- Embryologically, the cleft may affect the primary or/and secondary palate.
- Anatomically, the cleft is defined according to the involvement of the hard and soft palates.
- A complete cleft of the palate is defined as a cleft involving both the primary and secondary palates. Hence, a complete cleft involves the soft palate and the hard palate.
- The Veau classification (**FIG 1**) provides a clinically useful description of the cleft type according to the involvement of the alveolus, the hard palate, and the soft palate. It guides selection of the surgical treatment.²
- The von Langenbeck palatoplasty is most commonly employed for incomplete cleft palates, where the primary palate is unaffected (ie, soft palate and hard palate to incisive foramen) or where the primary palate was previously repaired (commonly with a superiorly based vomerine flap at the time of lip repair).^{1,3}
- Von Langenbeck palatoplasty is less commonly used to repair isolated clefts of the soft palate (Veau I) and mostly employed to repair clefts of the soft palate and secondary palate [hard palate posterior to the incisive foramen (Veau II)].

- This technique may also be modified for complete clefts and is named a hybrid procedure.⁴ This hybrid procedure employs the bipediced von Langenbeck flap on the greater segment and a unipedicled flap on the lesser segment. It is not used for the treatment of submucous clefts.
- Additionally, the von Langenbeck technique of a bipediced mucoperiosteal flap may be used for the repair of fistulae located in the hard palate or junction with the soft palate.

PATHOGENESIS

- The etiology of cleft palate is multifactorial: environment, teratogen exposure (alcohol, anticonvulsants, steroids, diazepam), nutrition, maternal infections (rubella, toxoplasmosis), and genetics.
- Cleft palate repair restores anatomical closure between the oral and nasal cavities.
- An unrepaired cleft palate may result in impaired breathing, feeding, speech, and hearing.

NATURAL HISTORY

- Orofacial clefting is the most common craniofacial birth defect, occurring in 1:750 live births.⁵
- The incidence of cleft palate alone is 1:2000, with a female-to-male ratio of 2:1.
- The incidence of cleft palate in combination with cleft lip is greater, estimated at 1:1000 with a reverse gender ratio.
- In the population of children with cleft lip and/or cleft palate (CL+/-P), approximately 50% will have CLP, 30% to 35% CP, and 15% to 20% CL.

FIG 1 • Veau classification of cleft palate types. I. Cleft of soft palate only. II. Cleft of secondary hard and soft palates. III. Unilateral cleft extending through secondary

hard and soft palate, through right or left primary palate, and through the alveolar process. IV. Bilateral cleft through secondary hard and soft palate, through bilateral primary palate and bilateral alveolar processes.

- Approximately 40% of CP patients will have a syndrome, and 15% of CLP will have a syndrome.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The diagnosis of a cleft palate is made by prenatal ultrasonography or by physical examination at birth and in early infancy. A detailed assessment is made of the child's breathing, feeding, growth, and development.
- Airway assessment must exclude the presence of sleep apnea and micro-/retrognathia.
- Assessment of growth and weight is key to identify and monitor feeding difficulty, gastroesophageal reflux, and the use of feeding aids (Haberman/Pigeon test).
- Hearing and middle ear function must be assessed and treated early by an otolaryngologist.
- The plastic surgeon should define the cleft palate type according to the anatomic structures involved, the laterality, width of the palate, and the presence/absence of a cleft lip.
- Also, the child should be assessed for associated anomalies suggestive of a syndrome: craniofacial dysmorphism, airway compromise, cardiac defects, ocular and auricular abnormalities, and musculoskeletal anomalies. A genetics referral is suggested if suspicious for a case of syndromic cleft palate.

DIFFERENTIAL DIAGNOSIS

- Syndromic cleft palate
 - Van der Woude syndrome
 - Stickler syndrome
 - Robin sequence
 - 22q11.2 deletion syndrome
 - Treacher Collins syndrome
 - Nager syndrome
 - Ectrodactyly-ectodermal dysplasia

- Klippel-Feil syndrome

NONOPERATIVE MANAGEMENT

- It is very uncommon not to repair a cleft palate.
- If the child is unable to undergo surgical treatment secondary to airway concerns or medical fitness, a palatal obturator may be considered.
 - Such patients should be reassessed on a regular basis (at least annually), as they may become sufficiently stable for delayed surgical correction of the cleft palate.

SURGICAL MANAGEMENT

- Cleft palate repair is ideally performed between 9 and 12 months of age, with the infant weighing greater than 8 kg.
- Airway and middle ear disease assessment is performed and treated prior to or simultaneously with cleft palate repair.
- Risks of the procedure are hemorrhage/hematoma, airway compromise, wound dehiscence, infection, oronasal fistula, flap necrosis, velopharyngeal insufficiency, and reduced midfacial growth.
- The main objectives of the cleft palate repair are:
 - To separate the oral and nasal cavities
 - To reposition the velar musculature for restoration of the velopharyngeal sphincter, in particular the reconstruction of the levator muscular sling
 - To improve Eustachian tube function
 - To minimize detrimental effects on subsequent maxillary growth
- The goals of the palatoplasty are to improve feeding and speech.
- The main steps of the procedure are:
 - Marking and elevation of bipediced mucoperiosteal flaps off the hard palate
 - Dissection and separation of the nasal mucosa, velar musculature, and oral mucosa
 - Careful dissection of pedicles (greater palatine artery)
 - Tension-free closure of nasal mucosal layer
 - Reconstruction of the velopharyngeal sphincter with repositioning of the levator sling
 - Recreation of the uvula
 - Closure of the oral mucosal layer

Preoperative Planning

- With the patient anesthetized, the width of the cleft is measured at the junction of soft and hard palate. The width of the cleft is important to predict difficulty of the cleft palate repair and anticipated amount of dissection required for closure.
- The von Langenbeck technique provides less flap mobilization relative to other techniques (two-flap palatoplasty). Thus, this technique is best reserved for narrow clefts.

Positioning

- The patient is positioned supine with shoulder roll to allow neck extension. An oral Rae tube, with the circuit directed caudally, is carefully taped centrally. Corneas are protected with eye taping.
- Access and visualization of the entire palate are very important and cannot be understated. It is especially important to ensure visualization from the uvulae to the anterior extent of the palate.
- It is essential for the surgeon to ensure positioning is correct prior to scrubbing. This will facilitate the procedure.
- The surgeon should have a headlight or lighted instruments for optimizing visualization in the confined space and a skilled attentive assistant.
- It is advantageous to have a bed that has Trendelenburg positioning capability. Some surgeons stand to perform palate surgery from below, but having the baby's head supported with the surgeon seated operating upside down provides the best exposure and is the preferred position by most surgeons.

Approach

- The aim of cleft palate surgery is tension-free closure of the palate oral and nasal mucosal layers and restoration of the velopharyngeal muscular sphincter.
- Difficulties anticipated include:
 - Access
 - Lighting
 - Bleeding obscuring visualization
- Surgical approaches differ with regard to the amount of dissection performed to achieve tension-free closure and muscle repositioning.
- Critical step is adequate exposure and dissection of tissues to provide comfort for the operating surgeon to achieve tension-free closure.
- Oral layer mobilization is largely dependent on careful mobilization of the

greater palatine artery from its periosteal sleeve.

- Nasal layer mobilization is largely dependent on careful mobilization of the mucosa as a sheet from its dense bony attachments.

TECHNIQUES

■ Markings

- Carefully insert an intraoral gag and a throat pack (it is the surgeon's responsibility to insert and remove).
- Mark the incision lines:
 - Along the medial edges of the cleft from the uvulae to the anterior extent of the cleft at the primary palate
 - Laterally at the junction of the hard palate and maxillary alveolus, extending from the posterior maxillary tubercle anteriorly to the level of the canine tooth (**TECH FIG 1**).
- Inject local anesthetic with adrenaline into the hard palate and soft palate (average of 8 mL).
 - The vasoconstrictive properties reduce blood loss and enhance visual field.
 - Local anesthetic also facilitates hydrodissection of the mucoperiosteal flaps off of the hard palate and tissue expansion for ease of layer dissection in the soft palate.
- Wait 8 minutes or until injection sites stop bleeding.

TECH FIG 1 • Incision markings of a von Langenbeck palatoplasty for cleft of the secondary palate.

■ Elevation of Oral Mucoperiosteal Flaps

- Perform incisions with needle tip cautery to reduce bleeding. Use a skin hook on the uvula or stay sutures for countertraction.
- Incisions, flap elevation, and pedicle dissection are done similarly on both the greater and lesser segments.
- Begin with lateral incisions: from the retromolar trigone along the junction of the alveolus and palate with diathermy down to the bone and slightly angled medially so as to avoid injury of developing teeth.
- For the medial incisions, palpate the posteromedial edge of the hard palate before incising to ensure the incision medially will be onto the bone (hard palate) as you can inadvertently cut into the nasal layer and do a “double cut” that reduces the available tissue for nasal layer closure (**TECH FIG 2A**).
- Oral palatal mucosa is susceptible to tearing so dissect continuously along the entire length of the lateral incision toward the cleft to elevate the mucoperiosteal flaps.

- Avoid “tunneling” as this can cause tearing of the hard palate mucosa due to dense periosteal attachments.
- Use a periosteal elevator to raise the mucoperiosteal flaps from lateral to medial beginning at the anterior extent of the incision (**TECH FIG 2B**).
- Dissect from anterior to posterior along the hard palate in sweeping motions toward the greater palatine foramina and posterior limit of the hard palate.

TECH FIG 2 • A. Incision of medial edge of cleft beginning at posterior-medial border of the hard palate, separating oral and nasal mucosal layers. **B.** Dissection of oral mucoperiosteal flaps.

■ Isolation of Greater Palatine Vessels

- As you approach the greater palatine artery at the posterolateral edge of the hard palate, the vessel becomes visible on the undersurface of the flap. The visibility of the pedicle is limited with this bipediced flap technique. Given the difficulty in visualization, the amount of dissection of the pedicle may be limited. Knowledge of the pedicle location will enable you to gently and circumferentially release the dense periosteal attachments around the pedicle.
 - A surface landmark for the pedicle is the dimpling in the mucosa near the posterior edge of the hard palate. This represents the dense periosteal attachments of the pedicle.
- Start laterally, and then work circumferentially around the foramina, staying

on the bone and taking care not to dissect into the artery or the leash of veins surrounding it.

- Staying on the bone during pedicle dissection is very important and rewarding for there are tethering ligaments that insert into the oral mucosa.
- Dissection directly off the bone facilitates the circumferential release of these ligaments, which otherwise make it exceedingly easy to tear the oral mucosa and injure the pedicle.
- Spreading of dissecting scissors parallel to the vascular pedicle will help to release some dense periosteal attachments; this should be done with care not to avulse the vessel.
- Previous hydrodissection during local anesthetic injection will also aid in finding the bloodless plane between the oral layer mucosal glands and the muscular layer.
- Complete circumferential pedicle dissection is achieved once the periosteal sleeve is released behind the greater palatine foramina, and the flaps can be mobilized toward the midline.
- It is critical for the surgeon to anticipate the location of the pedicle and appreciate the careful dissection to be completed with limited visibility, mainly using the lateral approach to perform the release.
- Once sufficiently mobilized, retract the flaps out of the surgical field with stay sutures, and secure to the intraoral gag/retractor.

■ Dissection and Separation of the Oral Mucosa, Nasal Mucosa, and Muscle

- Oral mucosa dissection: under magnification, dissect in the plane between oral mucosal glands and the muscle layer posteriorly in the soft palate from the edge of the bony palate to the uvula.
- Nasal mucosa dissection:
 - Mobilize the nasal mucoperiosteal layer with care, beginning on the lesser segment of the cleft. This requires the gradual and wide dissection of this continuous sheet of nasal mucosa, which is firmly attached to the hard palate along its medial and posterior edges, along the nasal surface of the bony palate and the medial surface of the medial pterygoid plate.
 - The elevation of the nasal layer anteriorly on the greater segment will necessitate elevation off the vomer.

- The nasal mucosa is even more unforgiving than the oral mucosa. Once a tear occurs, it is easy to propagate. Resist the temptation to tunnel before a whole edge has been liberated.
- To liberate the dense attachments of the medial hard palate, a Mitchell trimmer double-ended elevator or a similar blunt edged instrument is used.
 - The dissection starts at the cleft margin, scraping the oral surface of the bone until the edge of the nasal mucosa starts to be defined.
 - As the edge of the hard palate becomes apparent, elevate the nasal mucoperiosteum widely off the entire extent of the medial aspect of the hard palate.
- The judicious use of needlepoint diathermy on low setting can help to elevate firmly attached areas that are not easily released with the Mitchell trimmer.
- Once the edge of the nasal mucoperiosteal flap is defined, slide the trimmer around the corner of the hard palate onto the nasal surface of the bone staying right on the bone. If the edge is sufficiently liberated, sweep anteriorly and posteriorly to liberate the entire sheet off the nasal surface.
- If a portion of the edge is still attached, resist further sweeping until releasing the portion that remains tethered to prevent a tear.
- This dissection is continued to the posterior nasal spine.
 - At this juncture, there are always muscle attachments.
 - Release these aberrant velar muscle attachments with needlepoint diathermy.
- Continue dissection along the nasal surface following the posterior edge of the bone cephalad and lateral toward the medial surface of the medial pterygoid plate.
- Release the nasal mucoperiosteum directly off the bony surface of the medial surface of the medial pterygoid plate with careful dissection of the fibrous attachments.
 - Be patient and careful during the release of this densely adherent portion of the nasal mucosa working posteriorly and cephalad along the pterygoid plate and palatine bone.
 - Confirm complete release by directly visualizing the plane of the medial surface of the medial pterygoid plate.
 - If further release is required, the origin of the tensor veli palatini along the medial pterygoid plate may be severed to improve mobilization.

- The sheet of mucosa should now be freely mobile as one continuous sheet posteriorly and along the anterior medial hard palate.
- Attention is then turned to the greater segment.
 - The dissection of the nasal mucoperiosteal flap is identical posteriorly along the hard palate cleft margin.
 - Anteriorly, at the bony junction of the vomer and bony palate, the nasal mucoperiosteum is raised in continuity with the vomerine periosteum. This vomerine flap is raised cephalad directly off the bone and in continuity with the periosteum of the nasal surface of the hard palate.
- In a cleft of the secondary palate only, the caudal edge of the vomer is located in the midline of the two hard palate shelves.
 - The caudal vomer is incised in the midline and nasal mucoperiosteal flaps raised off each side of the vomer.
 - Both vomerine flaps are used for closure of the nasal lining anteriorly; each vomerine flap is secured to the ipsilateral hard palate nasal mucoperiosteal flap.
 - As you close the nasal lining from anterior to posterior, you will continue beyond the vomerine flaps and directly approximate nasal lining from the palatal shelves.

■ Closure of Nasal Mucosa

- Nasal layer closure is then commenced once assurance that the repair is tension free by checking that both sides are sufficiently liberated (**TECH FIG 3**).
- Meticulous closure is executed with knots tied on the nasal side.
- Small wedges are excised at the base of the oral surface of the uvula to assist closure.
 - Place eversion sutures during the closure of the uvulae to prevent notching or bifidity.
 - It is helpful to pare the musculus uvulae into a nasal and oral component during dissection so that musculus uvulae can be included in the suture closure of both oral and nasal layers of the uvula to further strengthen the closure.

TECH FIG 3 • Closure of nasal mucosal flaps from anterior extent of cleft to the uvula.

■ Dissection of the Muscle and Intravelar Veloplasty

- With the nasal layer completely closed, proceed with the muscle dissection and reconstruction of the velopharyngeal sphincter.
- Three steps are critical for muscle repositioning:
 - Identification and separation of levator veli palatini (LVP)
 - Velar musculature dissection and release from its attachments to the cleft margin and hard palate shelf
 - Velar musculature repositioning and repair
- Deep to the muscles inserted into the back of the bony hard palate, the LVP inserts abnormally at the cleft margin in the anterior half of the velum.
- Using a scalpel, sharply dissect the velar muscle layer off the nasal mucosa along the cleft margin. This is done with a paramedian incision lateral to the nasal mucosal closure line through the muscle until nasal mucosal surface is

identified.

- It is easiest to separate the muscle layer once the nasal mucosa has been repaired to give a “trampoline” effect, providing tactile feedback and countertraction during this careful dissection.
 - The bulk and breadth of the muscle widen as you dissect laterally. This is analogous to the changing depth of a swimming pool, with a shallow end (paramedian) becoming deeper as one progressively dissects laterally.
 - The velar musculature is raised off the nasal mucosa and separated from the tendinous fibers of the tensor veli palatini (TVP). This separation is done laterally along the hard palate shelf at the junction of “salmon pink” velar muscle fibers and tendinous fibers of the TVP.
 - The velar musculature is further dissected until it can be freely mobilized to lie parallel to the posterior hard palate margin and overlying the contralateral velar muscle bundle.
 - You have completed the levator dissection when the “salmon pink”-colored longitudinal fibers of the levator are identified emerging from the skull base and the entire dissected muscle is free to be reoriented to a more functionally effective position in the posterior half of the soft palate.
 - The dissection of the velar musculature is performed on both sides.
 - Repair the muscles, and reconstruct the levator muscular sling by suturing the muscles and securing with multiple sutures, knots facing the nasal surface.
 - Ensure proper hemostasis is achieved.
-

■ Closure of the Oral Mucosa

- Close the oral layer beginning with stay sutures placed anteriorly and progressing posteriorly toward the uvulae with horizontal mattress sutures. There is no attempt of push-back of the flaps for lengthening with a V-Y closure (**TECH FIG 4**).
- During oral layer closure, place some full-thickness sutures through both the oral and nasal layers just posterior to the hard palate shelf (anterior to muscle repair) to help obliterate the dead space and position the muscle repair.
- Place interrupted simple sutures between each of the mattress sutures.
- Attempt to minimize raw bone exposure by closing palatal flaps to the alveolus wherever possible.

- Recheck for adequate hemostasis, irrigate, and remove throat pack.
- If concerned for airway during postoperative period, consider nasopharyngeal tube insertion and a tongue stitch. Note that a tongue stitch is rarely used in our practice.

TECH FIG 4 • Closure of oral mucosa after medialization of the bipediced flaps.

PEARLS AND PITFALLS

Headlight and positioning

- Good lighting and access to the palate are important

Pedicle dissection

- Visibility of the greater palatine foramina is limited. The release is accomplished with careful and near-

	circumferential dissection from the lateral approach. Complete the dissection from the medial approach.
Hemostasis	■ Ensure meticulous hemostasis throughout the case to optimize visualization. ■ Judicious use of needlepoint diathermy. ■ Failure to do so may result in airway compromise, flap necrosis, and wound dehiscence.
Use needlepoint diathermy to make hard palate incisions	■ Controls bleeding and persisting ooze.
Work on broad front	■ Avoid tunneling during dissection.
Patience and precision during dissection especially around palatine foramina	■ Bleeding obscures view, and careless dissection risks injury to pedicle and vascularity of the flap.
Handle tissues with care	■ The nasal mucosa is especially susceptible to tears.
Inset palatal flaps with stay sutures to help control closure	■ Helps to put the most difficult sutures anteriorly with stay sutures to judge closure and maintains good exposure.
Do not attempt closure until all layers are sufficiently mobilized	■ Prevents tearing. ■ If sutures are prematurely placed, further attempts to mobilize tissue are more likely to result in tears. Prematurely suturing may also result in tears if tension is still present.
Oronasal fistula	■ Critical to achieve adequate tissue dissection, perfect approximation, and apposition of tissue layers with meticulous suture technique to prevent fistulae.

POSTOPERATIVE CARE

- Nasopharyngeal tube as required.
- Remove tongue stitch in recovery if used.
- Analgesia to reduce blood pressure and distress (24 hours of intravenous opioids).

- Encourage feeding.
- Postoperative visit in 4 weeks.

OUTCOMES

- Primary von Langenbeck palatoplasty with levator reconstruction provides a reliable repair and good speech outcomes with 89% of patients having acceptable or normal speech.
 - Velopharyngeal insufficiency necessitated surgical correction in 11% of patients.
- The fistula rate of a cleft palate repair with a bipedicle flap technique is 10.2% (95% CI, 6.3% to 15%) according to a systematic review of international data.⁶
 - There was an observed trend toward higher fistula rates with bipedicle compared to unipedicle flap technique.
- The effect of palatoplasty on maxillary facial retrusion is controversial. Inherent maxillary growth deficiency, secondary scarring from palatal flap elevation, and timing of repair are all contributing factors to midfacial retrusion. Deleterious growth has been shown to be greatest in patients treated by Veau push-back technique.⁷
 - Further long-term studies are required to compare the effect of palatal flap technique on maxillary growth restriction.

COMPLICATIONS

- Bleeding is a feared complication as it may lead to an emergency with airway obstruction and respiratory compromise. Additionally, hematoma may lead to compression of the pedicle or flap, with resultant flap necrosis, wound dehiscence, and oronasal fistulae.
 - To prevent this complication, vigilant hemostasis is an absolute necessity, and adequate postoperative analgesia avoids stressing the repairs.
- Airway obstruction may occur in the absence of hemorrhage, and a tongue stitch or nasopharyngeal tube may assist in preventing obstruction in infants at risk.
- Flap necrosis is rare and avoidable with careful dissection and release of the periosteal sleeve of the greater palatine pedicle.
- Infection and wound dehiscence leading to oronasal fistulae are detrimental.
 - A small fistula secondary to delayed wound healing may heal with conservative measures.

- Failure of closure may necessitate reoperation with re-elevation and closure of oral and nasal flaps, as well as possible augmentation using local flaps and/or biologic adjuncts.

CHAPTER Sommerlad Palatoplasty

T. Guy Thorburn

DEFINITION

- Cleft palate repairs can be broadly classified into straight-line repairs (such as the Sommerlad technique) vs Z-plasty repairs (such as the Furlow technique).
- Otto Kriens proposed the intravelar veloplasty based upon his work on the anatomy of the cleft palate.¹
 - Sommerlad then developed this dissection into a more radical procedure and popularized the technique.
- The underlying principle is identification and repositioning of the soft palate muscles, before connecting the levator muscle mechanisms from the two sides of the soft palate.

ANATOMY

- The key functional issue in CP or SMCP is that the levator muscle mechanism is not in continuity on the two sides. In addition, the fibers become tethered to the posterior border of the hard palate.
 - Successful functional palate repair therefore requires repair of the “levator sling” as well as closure of the tissues across the cleft.
- The tethering to the hard palate seems to be an equal problem in differing types of cleft: whether unilateral or bilateral cleft lip and palate, cleft palate only, or submucous cleft palate.
- The key functional muscle is the levator palatini, but the surrounding muscle/aponeurotic tissue is kept in continuity to allow more reliable tissue handling and repositioning and subsequent suturing.
 - Of note, the levator sits on the nasal aspect of the soft palate and so becomes visible only when the dissection is well underway.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The initial assessment of the newborn with a cleft involving a palate would usually be alongside a pediatrician and includes:
 - Pregnancy and birth history (including information from any antenatal testing), gestation, birth weight, and Apgar scores.
 - Initial assessment of cleft type and any related anomalies, including any airway concerns suggesting Robin sequence.
 - Medical, drug, and allergy histories.
 - Family history of clefts, other major health problems, or anesthetic problems and any genetic diagnosis.
 - Feeding history, including bottle type (eg, squeezzy bottle, free flow, Haberman), current weight, maximum percentage weight loss and number of days to regain birth weight, and volume/duration/frequency of feeds.
 - Physical examination to assess the upper airways, cleft type, cleft width and how much deficiency there is of surrounding tissues, as well as any related anomalies or dysmorphic features. The pediatrician would then complete a fully newborn examination looking in particular for related health issues such as cardiac, respiratory, renal, or neurological signs.

IMAGING

- No routine preoperative imaging is required for typical clefts. For older children presenting with SMCP or velopharyngeal incompetence (VPI), assessment with a speech lateral videofluoroscopy helps to evaluate the position of the velum during phonation and relative size of the soft palate to the size of the pharynx.
- Standardized preoperative clinical photos should be taken as these are invaluable when assessing outcomes many years later.

SURGICAL MANAGEMENT

Preoperative Planning

- A key aspect of successful cleft palate repair is optimizing the patient prior to surgery. A pediatrician is a crucial member of the cleft team.
- Although there is much discussion of age at palate repair, different team protocols vary from around 3 months old to 15 months or more.
 - Very young babies will tend to be more susceptible to airway compromise around the time of surgery.

- Delaying repair until much older and speech has developed has been associated with poorer speech outcomes, particularly related to articulatory errors.
- Our team protocol is for palate repair around 8 to 12 months (corrected for prematurity), but our emphasis is much more on ensuring that the child is well and thriving as surgery approaches.
- If the child is not growing along his or her expected centiles (with growth plotted on the appropriate chart for syndromic children), this should be addressed before surgery.
- We routinely postpone for about 4 weeks if children have upper respiratory tract infections.
- By following this approach, we have seen a significant reduction in fistulae and concerns with speech function.
- Routine blood tests or cross match samples are not required, unless the child is known to have a specific risk factor.
- For children with cardiac or respiratory problems, an up-to-date echocardiogram or sleep study may be relevant.

Positioning

- A Rae uncuffed or microcuffed tube is positioned in the midline and secured to the lower face.
- The taping of the tube needs to be secure but avoiding taping the mouth closed or limiting access. Taping in a V shape along the line of the mandible avoids displacing the tapes when the mouth gag is opened.
- The child is placed supine on a warming blanket, with the head at the very end of the operating table.
- A large horseshoe gel head ring is placed under the shoulders and around the head to provide support without overextending the neck.
- A head drape is applied, and the face is prepped.
- The table is tilted to a slight head-up position.
- An operating microscope is used for the procedure. The height of the table is adjusted once the microscope has been brought into place (adjusted according to whether the surgeon prefers to sit or stand).
- A modified Dingman mouth gag is placed.
- A throat pack is placed, and a marker sticker put across the drapes as a reminder to ensure it is removed at the end.

- The sticker is placed so that the drapes cannot be removed without needing to disturb the warning sticker.
- The throat pack is also included in the scrub nurse count as an additional precaution.
- The nose and mouth are rinsed with aqueous chlorhexidine solution.

FIG 1 • Marking the incisions at the margin of the cleft.

Approach

- The width of the cleft is measured. The extent of the cleft and any unusual features are noted.
- The incisions are marked with pen and ink (**FIG 1**).
 - Depending on the extent and shape of the anterior edge of the cleft, either a horseshoe shape or a triangular flap can be marked anteriorly.
 - The line of the incision in the soft palate can be identified by the pale line where the nasal mucosa meets the oral mucosa along the margin of the cleft.
- For very wide clefts, lateral von Langenbeck incisions can be marked at the outset, or these can be decided later in the procedure after the closing tension around the hard palate-soft palate junction is apparent.
- Tension is a factor of the soft tissue cleft width, the width of the lateral shelves of the palate, the elasticity of the tissue, and how vertical the shelves were sitting (which gives a “drawbridge effect”).

TECHNIQUES

■ Hard Palate

Incisions and Dissection

- Levobupivacaine or bupivacaine long-acting local anesthetic with adrenaline 1:100 000 is infiltrated and left about 8 minutes for vasoconstriction.
 - The injection is used to help hydrodissect the hard palate subperiosteal layer and the vomer flaps if these are being used (**TECH FIG 1A**)
- The incision is begun along the cleft margin (or in the midline for a SMCP or rerepair).
 - For complete clefts of the palate, it is usually easier to start with the posterior two-thirds of the hard palate extending across the hard palate-soft palate junction, then to move on to the very anterior portion of the cleft, and finally to move on to the posterior soft palate and uvula (**TECH FIG 1B**).
- For clefts involving the hard palate, use a no. 15 blade to incise carefully down to the bone along the margin of the hard palate and 3 to 5 mm past the hard palate-soft palate junction and elevate subperiosteally with a periosteal elevator or Warwick-James elevator (**TECH FIG 1C,D**).

TECH FIG 1 • **A.** Local anesthetic is injected to hydrodissect the oral mucoperiosteal flaps. **B.** A no. 15 blade is used to incise the margin of the cleft, starting with the anterior third of the soft palate up to the posterior two-thirds of the hard palate at this stage. **C.** Using the Warwick-James elevator with a wriggling movement helps to elevate the oral flaps over the hard palate. Switching between the Warwick-James elevator and a periosteal elevator makes different parts of the dissection easier. **D.** The Warwick-James elevator is used to lift the most anterior portion of the hard palate flaps. **E.** Releasing the tethered salivary gland from just behind the posterior nasal spine. **F.** The dental mirror is showing

the underside of the oral layer flap to demonstrate the extent of the dissection laterally, including out toward the great palatine artery. **G.** A no. 12 blade is aimed posteriorly to incise the margin of the uvula and posterior third of the soft palate.

- Be careful approaching the posterior nasal spine as the tissues are more adherent here, and it is easy to tear the oral layer if there is a tethered salivary gland at this point. Switching between a no. 15 blade and periosteal elevator is usually necessary (**TECH FIG 1E**).
- For wider clefts, a more radical hard palate dissection is required to reduce the tension when closing.
- The Warwick-James elevators and dental flat plastic can be alternated to lift more laterally and, if needed, to free up the periosteal attachments around the greater palatine artery to improve mobilization (**TECH FIG 1F**).
- For incising the margin of the rest of the soft palate and back to the uvula, a no. 12 blade tends to be easiest (**TECH FIG 1G**).
- Depending on the cleft type, it may be necessary to raise vomer flaps to help close the nasal layer without tension.
- For wide clefts, it may be useful to incorporate a sphenoid flap in the nasal layer closure.
 - This is a flag-shaped extension to one of the vomer flaps, which rotates with inseting to provide additional tissue to the nasal layer around the hard palate-soft palate junction where it is usually tightest.²

Elevation of the Nasal Layer

- After raising the vomer flaps, elevate the nasal layer off the hard palate (again in a subperiosteal plane) with a periosteal elevator or dental flat plastic.
- Mobilize the nasal layer off the hard palate bony shelves, taking care not to damage the nasal layer (**TECH FIG 2**).

TECH FIG 2 • The stages of dissecting the nasal layer mucoperiosteal flap from the hard palate bony shelf. (1) Using a periosteal elevator with the spoon facing nasally, gently lift the periosteum off the margin of the bone with small movements. (2) Rotate periosteal elevator 180 degrees, so spoon faces orally, and insert it subperiosteally on nasal aspect of posterior edge of the bony shelf of the hard palate. (3) Wiggle and rotate spoon across the postnasal spine, the most adherent point. (Always return to position 2 if the periosteal elevator slips out of place.) (4) Continue to make wiggling and rotating movements with the periosteal elevator from the postnasal spine anteriorly.

■ Start by using a periosteal elevator to gently free the periosteum off the

margin of the bone and postnasal spine.

- Next, use a periosteal elevator to wriggle beneath the bone shelf in a subperiosteal plane, working from the area of the tensor aponeurosis, around the postnasal spine, and then onto the medial margin.

von Langenbeck–Type Releasing Incisions

- For wide clefts, it may be necessary to use lateral von Langenbeck–type releasing incisions.
 - This decision may be clear at this point in the operation, in which case making early incisions can be efficient.
 - When the decision is less obvious, continue with the rest of the dissection, and the releasing incision can be made immediately prior to oral layer closure.
- When a von Langenbeck–type releasing incision is required, mark out a lazy S incision along the medial aspect of the alveolus and around its posterior limit to overlies the hamulus (**TECH FIG 3A**). The incision is kept as short as possible while allowing good mobilization of the oral layer flaps.
 - Local anesthetic with adrenaline is injected to help with hydrodissection and vasoconstriction: it is important to have a clear view to reduce the risk of damage to the greater palatine vessels.
- The incision is started in the hard palate with a no. 15 blade, incising down through periosteum at the medial base of the alveolus but ensuring that you stay lateral to the course of the artery.
- The incision is extended more superficially around the tubercle and over the hamulus.
 - A periosteal elevator is used to elevate the flap subperiosteally (**TECH FIG 3B**). It is often easier to have a second periosteal elevator to elevate simultaneously the tissues via the previous incision at the medial aspect of the palate until the two instruments meet.
 - It is then possible to work posteriorly, and one should elevate carefully the tissues around the greater palatine artery until the oral flap is sufficiently mobile to meet the opposite flap in the midline.

TECH FIG 3 • **A.** Marking for the incision of lateral releasing incision around the posterior aspect of the alveolus on the left, using a lazy S shape. **B.** Following incision of the mucosa, a periosteal elevator is used to lift under the periosteum and mobilize the flap.

■ Oral Layer

- To separate the oral layer from the muscle layer, the periosteal elevator or a dental flat plastic is swept back from the posterior margin of the palatal bone shelf (**TECH FIG 4**).
 - The plane is easier to develop laterally, near the hamulus, so the process starts here and then moves medially.
- A no. 12 blade is then used to incise posteriorly along the margin of the cleft toward the uvula.

TECH FIG 4 • The periosteal elevator is slid off the

back of the hard palate shelf to separate the oral layer off the muscle fibers. Note the tip of the periosteal elevator is just reaching the hamulus, as the plane is easier to develop more laterally.

■ Nasal Layer

- Use interrupted sutures to close the nasal layer, incorporating vomer flaps anteriorly if available and needed.
 - A resorbable monofilament suture is used, preferably with a round or tapercut needle to avoid inadvertent tears of the mucosa. We use 5-0 Monocryl plus on a round-bodied needle for this closure.
 - The bites pick up more of the glandular tissue, with only a small amount of nasal mucosa, and knots are laid on the nasal aspect. This helps to evert the edges toward the nasal aspect (**TECH FIG 5**).
- If the nasal layer is too tight for closure around the hard palate-soft palate junction, then leave closure of this section until after the muscle dissection.

TECH FIG 5 • **A.** Suturing of the nasal layer, with the knots placed on the nasal aspect. Interrupted sutures are placed, working posteriorly toward the uvula. **B.** Suturing the uvula using horizontal mattress sutures to pick up the fibrous “core” of the uvula, as the mucosa tends to become friable in this area.

■ Muscle Dissection of the Nasal layer

- Applying topical 1:1000 adrenaline on neuro patties for about 5 minutes

before beginning the muscle dissection provides excellent vasoconstriction and facilitates the subsequent dissection (**TECH FIG 6A**).

- To make access easier for the next stage, a stay suture can be used to hold the oral flaps out of the way (**TECH FIG 6B**).
- Closure of the nasal layer has now pulled the soft palate muscles out to length, with the resultant tension helping with the next stage of dissection.
 - A fresh no. 15 blade is used for each side of the palate. Alternatively, some surgeons find it easier to use a straight Beaver blade (**TECH FIG 6C**).
- Start on each side by incising the posterior border of the muscles; this will leave behind a triangular block of fibrous/glandular tissue around the base of the uvula (**TECH FIG 6D**).
- Next, incise the medial margin of the muscle (**TECH FIG 6E**).
- Finally, incise the tensor aponeurosis anteriorly (**TECH FIG 6F**), and extend posterolaterally to divide the tendinous material from the hamulus.
 - Bipolar diathermy is then used sparingly to assist with the lateral dissection, but the aim is to preserve as much of the vascular supply to the levator muscle as possible (**TECH FIG 6G**).
- A dental flat plastic is then used to slide between the remaining levator and the nasal layer and particularly to free up any fascial sheath that can sit on the distal aspect of the muscle and restrict its repositioning (**TECH FIG 6H**).
- When it has been properly dissected, the levator muscle should easily be displaced to the posterior end of the soft palate (**TECH FIG 6I,J**).

TECH FIG 6 • A. Neurosurgical patties have been placed in contact with the exposed muscle and topical

adrenaline dripped on with a 1-mL syringe. **B.** While the topical adrenaline is taking effect, a stay suture is inserted in the oral layer of the midsoft palate to help with retraction for the next stage. **C.** Using a straight Beaver blade as an alternative to a no. 15 blade. **D.** Diagram showing the dissection of the soft palate muscles. (Oral layer not shown to allow clearer visualization.) **E.** Dissecting the medial extent of the soft palate muscles. The levator muscle is still not yet visible at this point in the dissection. **F.** Incision of the tensor aponeurosis off the back of the hard palate. Note how the forceps are used to tension the muscle toward the midline, which helps the dissection and reduces the chance of “buttonholing” the nasal layer. The sharp incision continues laterally to free the muscle from the hamulus. **G.** Key landmarks when freeing to muscle and of bipolar dissection. **H.** A dental flat plastic is slid between the levator (just visible as the slightly bluish muscle fibers under the brighter pink pharyngeus muscle fibers) and the nasal layer to complete the dissection. Before **(I)** and after **(J)** views of the muscles on the right side of the soft palate to show the extent of repositioning after dissection is complete.

■ Closure

- The nasal layer closure can now be completed if necessary.
 - If the nasal layer has no holes, drainage holes can be incised laterally if required.
- The two sides of the muscle are now sutured across the midline (**TECH FIG 7A,B**).
 - We use a nonabsorbable monofilament suture such as 5-0 nylon to place reliable knots, minimize trauma to the muscle, and avoid inflammatory

reaction from resorption.

- There is also the potential benefit that the sutures act as a useful marker of the levator position if it becomes necessary to re-explore the palate in the future. A locked mattress suture (similar to a Kessler stitch) is used.
- It is important to avoid tying the suture too tightly as this would strangulate the muscle with any postoperative swelling.
- It is also essential to cut the suture extremely short, right on the knot, so the knots can be laid flat as reef knots.
- The oral layer is closed with looped mattress sutures using a resorbable monofilament suture such as 4-0 Monocryl.
- Modifying the mattress suture that sits just anterior to the muscle can close off the dead space between the oral and nasal flaps in the soft palate (**TECH FIG 7C**).
- By picking up a bite of the fibrous/glandular tissue that was left behind on the nasal layer as the muscle was dissected, the mattress suture closes the two layers together (**TECH FIG 7D**).
- Finally, after closure is complete, the mouth is rinsed out, a nasal suction catheter is used to ensure there is no blood clot in the postnasal space, and if a throat pack was used, this is removed (**TECH FIG 7E**).

TECH FIG 7 • A. The mattress suture is placed in the muscle, aiming with each transverse bite to pick up the levator fibers (on the underside) as well as the aponeurosis tissue for a more reliable closure. **B.** The muscles on each side sitting at the posterior extent of the soft palate after suturing. **C.** Illustration (oral layer omitted) of the suture to appose the muscles on the two sides, just prior to tying. Locked mattress sutures pick up both keratin fibers (underneath) and tough tender aponeurosis tissue (anteriorly and on top) with each bite. **D.** The needle picks up a bite of the fibrous/glandular tissue that has been left attached to the nasal layer. **E.** The looped mattress suture, including the bite of the nasal layer, just prior to tying.

PEARLS AND PITFALLS

Timing of surgery	■ Careful optimization of the baby prior to surgery is important, progressive gain in length and weight as documented in a growth chart is a useful indicator—a thriving baby at the time of surgery is more important than a specific age.
Shared airway	■ As with all “shared airway” surgery, it is important for the anesthetist and surgeon to communicate well with each other—the WHO checklist and team brief are very useful for this.
Protecting the mouth and commissures	■ Steri-Strips are placed to protect the corners of the mouth from abrasion by instruments.
Operative microscope	■ The routine use of the operative microscope for palate repair gives excellent lighting and visualization of the operative field. It is also very helpful for giving trainees a better view and involvement, as well as reducing the strain on the surgeon’s neck.
Muscle dissection	■ The key to dissecting the muscles (without putting holes in the nasal layer) is to place tension on the tissues by using a skin hook or forceps to draw the muscle bulk toward the midline and then to stroke the curve of the blade to get a neat division. The vascular plexus that is seen immediately superficial to the nasal layer is a useful marker.
Draping the patient	■ We use a clear plastic drape over the trunk, which allows the anesthetist to see the endotracheal tube and circuit without disturbing the surgical field. We avoid any adhesive drapes near the endotracheal tube because these have the potential to catch and dislodge the airway.
Postoperative elevation	■ Nursing the baby “head-up” in the recovery room and on the ward after surgery is very helpful for reducing postoperative swelling—cuddling the baby over the parent’s shoulder tends to give ideal positioning.

POSTOPERATIVE CARE

- Topping up the local anesthesia with a long-acting agent at the very end of the

operation is useful for postoperative comfort and feeding.

- Nurse the baby with the head elevated.
- Babies can be offered feeds straight away once they are awake.
- Monitor airway and oxygen saturation, especially during the first night after surgery.

OUTCOMES

- The main outcome measures for cleft palate repair are fistula rate, structural speech problem rate, and impact on maxillary growth.³
- Negative outcomes in any of these parameters can lead to the need for secondary surgery for their correction.
- Sommerlad reported approximately 5% secondary surgery rates for VPI with a 10-year follow-up.⁴
 - He reported fistula rates that vary considerably by cleft type—35% in bilateral cleft lip and palate but an average of 12% in other cleft types.

COMPLICATIONS

- Infection, significant bleeding, and transfusion are all rare after palate surgery.
- Airway compromise is a potential risk, especially in babies with Pierre Robin sequence and in younger or smaller babies.
- Fistula is often reported around the hard palate-soft palate junction, but there is wide variation between series and the extent and width of the cleft palate can be a major factor in the fistula rate.
- Speech problems may occur for a variety of reasons, to include VPI and/or articulatory errors characteristic of cleft type.

CHAPTER Two-Flap Palatoplasty

David K. Chong, Kathryn V. Isaac, and Kenneth E. Salyer

DEFINITION

- Cleft palate is the failure of fusion of the palatal shelves during embryological development.
- Cleft palate may occur in isolation or in combination with a cleft lip. It may occur as part of a syndrome or in the absence of associated anomalies.
- A cleft of the palate may lead to feeding difficulties, speech impairment, chronic Eustachian tube dysfunction, hearing loss, and altered facial growth.
- Varying surgical approaches for cleft palate repair are utilized depending on the type of cleft palate and beliefs regarding facial growth and speech repercussions.

ANATOMY

- Embryologically, the cleft may affect the primary or/and secondary palate.
- Anatomically, the cleft is defined according to the involvement of the hard and soft palate.
- The hard palate is the bony palate, and surgical anatomy involves
 - Palatine process of maxilla
 - Horizontal plate of palatine bone
 - Hook of hamulus and pterygoid plates of sphenoid bone
 - Vomer/septum
 - Greater palatine foramina
- Soft palate is the mobile part of the palate, and surgical anatomy involves
 - Levator veli palatini
 - Tensor veli palatini aponeurosis
 - Palatopharyngeus

- Palatoglossus
- The Veau classification provides a clinically useful description of the cleft type according to the involvement of the alveolus, the hard palate, and the soft palate. It guides selection of the surgical treatment.
- The two-flap palatoplasty is most commonly performed for clefts of the hard and soft palate. It is not commonly used for isolated clefts of the soft palate and is not used for submucous clefts.

PATHOGENESIS

- The etiology of cleft palate is multifactorial: environment, teratogen exposure (alcohol, anticonvulsants, steroids, diazepam), nutrition, maternal infections (rubella, toxoplasmosis), and genetics.
- Cleft palate repair restores anatomical closure between the oral and nasal cavities.
- An unrepaired cleft palate may result in impaired:
 - Breathing
 - Feeding
 - Speech
 - Hearing

NATURAL HISTORY

- Orofacial clefting is the most common craniofacial birth defect, occurring in 1:750 live births.
- The incidence of cleft palate alone is 1:2000, with a female-to-male ratio of 2:1.
- The incidence of cleft palate in combination with cleft lip is greater, estimated at 1:1000 with a reverse gender ratio.
- In the population of children with cleft lip and/or cleft palate (CL+/-P), approximately 50% will have CLP, 30% to 35% CP, and 15% to 20% CL.
- Approximately 40% of CP patients will have a syndrome, and 15% of CLP will have a syndrome.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The diagnosis of a cleft palate is made by prenatal ultrasonography or by physical examination at birth and in early infancy. A detailed assessment is made of the child's breathing, feeding, growth, and development.
- Airway assessment must exclude presence of sleep apnea and micro-

/retrognathia.

- Assessment of growth and weight is key to identify and monitor feeding difficulty, gastroesophageal reflux, and use of feeding aids (Haberman/Pigeon teat).
- Hearing and middle ear function must be assessed and treated early by an otolaryngologist.
- The plastic surgeon should define the cleft palate type according to the anatomic structures involved, the laterality, width of the palate, and presence/absence of a cleft lip.
- Also, the child should be assessed for associated anomalies suggestive of a syndrome: craniofacial dysmorphism, airway compromise, cardiac defects, ocular and auricular abnormalities, and musculoskeletal anomalies. A genetics referral is suggested if suspicious of syndromic cleft palate.¹

DIFFERENTIAL DIAGNOSIS

- Syndromic cleft palate
 - van der Woude syndrome
 - Stickler syndrome
 - Robin sequence
 - 22q11.2 deletion syndrome
 - Treacher Collins syndrome
 - Nager syndrome
 - Ectrodactyly-ectodermal dysplasia
 - Klippel-Feil syndrome

NONOPERATIVE MANAGEMENT

- It is very uncommon not to repair a cleft palate.
- If the child is unable to undergo surgical treatment secondary to airway concerns or medical fitness, a palatal obturator may be considered.

SURGICAL MANAGEMENT

- Cleft palate repair is ideally performed between 9 and 12 months of age,² with the infant weighing greater than 8 kg.
- Airway and middle ear disease assessment is performed and treated prior to or simultaneously with cleft palate repair.
- Risks of the procedure are hemorrhage/hematoma, airway compromise, wound dehiscence, infection, oronasal fistula, flap necrosis, velopharyngeal

insufficiency, and reduced midfacial growth.

- The main objectives of the cleft palate repair are as follows:
 - To separate the oral and nasal cavities
 - To reposition to the velar musculature for restoration of the velopharyngeal sphincter, in particular the reconstruction of the levator muscular sling
 - To improve Eustachian tube function
 - To minimize detrimental effects on subsequent maxillary growth
- The main steps of the procedure are (a) marking and elevation of mucoperiosteal flaps off the hard palate; (b) isolation and lengthening of pedicles (greater palatine artery) for mobilization of the oral mucoperiosteal flaps; (c) dissection and separation of the nasal mucosa, velar musculature, and oral mucosa; (d) tension-free closure of nasal mucosal layer; (e) reconstruction of the velopharyngeal sphincter with repositioning of the levator sling; (f) recreation of the uvula; and (g) closure of the oral mucosal layer.

Preoperative Planning

- Active or passive dentofacial orthopedics is utilized for aligning the cleft maxillary arches by many teams today and is applied in the first few weeks of infancy. The orthopedic device is discontinued once the maxillary arches have been satisfactorily repositioned.
- With the patient anesthetized, the width of the cleft is measured at the junction of the soft palate and hard palate. The width of the cleft is important to predict difficulty of the cleft palate repair and anticipated amount of dissection required for closure. A cleft gap of:
 - Less than 11 mm closes with ease
 - 12 to 16 mm will require more extensive dissection to mobilize the greater palatine vessel and achieve nasal lining mobilization
 - Greater than 17 mm will require special maneuvers detailed below to achieve tension-free closure (greater palatine foramina osteotomy)

Positioning

- The patient is positioned supine with shoulder roll to allow neck extension. A south-facing oral RAE tube is carefully taped centrally with a mesentery. Corneas are protected with eye taping.
- Access and visualization of the entire palate is very important and cannot be understated. It is especially important to ensure visualization from the uvuli to the anterior extent of the palate.

- It is essential for the surgeon to ensure that positioning is correct prior to scrubbing. This will facilitate the procedure.
- The surgeon should have a headlight or lighted instruments for optimizing visualization in the confined space and a skilled attentive assistant. It is also advantageous to have a bed that allows for Trendelenburg positioning. Some surgeons stand to perform palate surgery from below but having the baby's head supported with the surgeon seated operating upside down provides the best exposure and is the preferred position by many surgeons.

Approach

- The aim of cleft palate surgery is tension-free closure of the palate oral and nasal mucosal layers and restoration of the velopharyngeal muscular sphincter.
- Difficulties anticipated include the following:
 - Access
 - Lighting
 - Unforgiving tissue
 - Bleeding obscuring visualization
- Surgical approaches differ with regard to the amount of dissection performed to achieve tension-free closure and muscle repositioning.
- Importance lies in adequate exposure and dissection of tissues to allow comfort for the operating surgeon to achieve tension-free closure.
- Oral layer mobilization is largely dependent on careful mobilization of the greater palatine artery from its periosteal sleeve.
- Nasal layer mobilization is largely dependent on careful mobilization of the mucosa as a sheet from its dense bony attachments.

TECHNIQUES

■ Two-Flap Palatoplasty for a Unilateral Complete Cleft Palate

Markings

- Carefully insert an intraoral gag and a throat pack (it is the surgeon's responsibility to insert and remove).

- Mark the incision lines:
 - Along the medial edges of the cleft from the uvuli to the anterior junction of the hard palate and alveolus
 - Laterally at the junction of the hard palate and maxillary alveolus, extending from the posterior maxillary tubercle to the anterior medial marking (**TECH FIG 1**)
- Inject local anesthetic with adrenaline into the hard palate and soft palate (average of 8 mL). The vasoconstrictive properties reduce blood loss and obstruction of the visual field. Local anesthetic also allows for hydrodissection of the mucoperiosteal flaps off of the hard palate and tissue expansion for ease of layer dissection in the soft palate.
- Wait 8 minutes or until injection sites stop bleeding.

Elevation of Oral Mucoperiosteal Flaps

- Perform incisions with needle tip cautery to reduce bleeding. Use a skin hook on the uvula or stay sutures for countertraction.
- Incisions, flap elevation, and pedicle dissection are done similarly on both the greater and lesser segments.
- Begin with lateral incisions: from the retromolar trigone along the junction of the alveolus and palate with diathermy down to bone and slightly angled medially to avoid injury of developing teeth.
- For the medial incisions, palpate the posteromedial edge of the hard palate before incising to ensure that the incision medially will be onto the bone (hard palate) as you can inadvertently cut into the nasal layer and do a “double cut” that reduces the available tissue for nasal layer closure. The incision medially is made with a scalpel.

TECH FIG 1 • Markings of a two-flap palatoplasty for a unilateral complete cleft palate.

- Oral palatal mucosa is susceptible to tearing, so dissect continuously along the entire length of the lateral incision toward the cleft to elevate the mucoperiosteal flaps. Avoid “tunneling” as this can cause tearing of the hard palate mucosa due to dense periosteal attachments.
- Use a periosteal elevator to raise the mucoperiosteal flaps from lateral to medial (**TECH FIG 2A**).
- Then, use a skin hook at the leading anterior edge of the flap and dissect from anterior to posterior along the hard palate in sweeping motions toward the greater palatine foramina and posterior limit of the hard palate (**TECH FIG 2B**).

Isolation of Greater Palatine Vessels

- As you approach the greater palatine artery at the posterolateral edge of the hard palate, the vessel becomes visible on the undersurface of the flap.

TECH FIG 2 • A. Dissection of the oral mucoperiosteal flaps. **B.** Elevation of the oral mucoperiosteal flap toward the pedicle, located posteriorly in the greater palatine foramina.

- The palatine artery has a circle of dense periosteal attachments around it.
- Carefully dissect starting anterior and then working circumferentially around the foramina, staying on bone and taking care not to dissect into the artery or the leash of veins surrounding it.
- To completely release the pedicle from its periosteal sleeve, careful and complete release of the periosteal attachments must be achieved by dissecting the flap directly off the posterior edge of the palatine bone.
- Staying on bone during pedicle dissection is very important and rewarding as there are tethering ligaments that insert into the oral mucosa.
- Dissection directly off bone facilitates the circumferential release of these ligaments, which otherwise make it exceedingly easy to tear the oral mucosa and injure the pedicle.
- Previous hydrodissection during local anesthetic injection will also aid in finding the bloodless plane between the oral layer mucosal glands and the muscular layer.
- Complete circumferential pedicle dissection is achieved once the periosteal sleeve is released behind the greater palatine foramina and velar muscle

attachments to the posterior edge of the hard palate are visualized (**TECH FIG 3**).

- It is critical for the surgeon to approach the release of the periosteal sleeve patiently with gentle dissection and successive wider approach, which will allow the palatine artery to finally be freed without tearing the mucosa or creating excessive bleeding.
- Once pedicle dissection is achieved, use gentle traction with scissors to tease the vessel free out of the foramina. This will create enough freedom to close most palatal clefts.
- Very occasionally in the widest of clefts (>16 mm), osteotomy of the posterior wall of the foramina is required.
- Once sufficiently mobilized, retract the flaps out of the surgical field with stay sutures and secure to the intraoral gag/retractor.

TECH FIG 3 • Oral mucoperiosteal flap elevation is completed: pedicles are mobilized and velar musculature is visualized attached along the posterior

hard palate.

- Under magnification, dissect in the plane between oral mucosal glands and the muscle layer posteriorly in the soft palate from the edge of the bony palate to the uvula.

Dissection of the Nasal Mucoperiosteum

- Mobilize the nasal mucoperiosteal layer with care, beginning on the lesser segment of the cleft. This requires the gradual and wide dissection of this continuous sheet of nasal mucosa, which is firmly attached to the hard palate along its medial and posterior edges, along the nasal surface of the bony palate and the medial surface of the medial pterygoid plate. The elevation of the nasal layer anteriorly on the greater segment will necessitate elevation off of the vomer.
 - The nasal mucosa is even more unforgiving than the oral mucosa, and once a tear occurs, it is very easy to propagate. Resist the temptation to tunnel before a whole edge has been liberated.
- Use a Mitchell's trimmer or similar blunt-edged instrument, starting at the cleft margin, and scrape the oral surface of the bone until the edge of the nasal mucosa starts to be defined and liberate the dense attachments to the medial hard palate. As the edge becomes apparent, elevate the nasal mucoperiosteum widely off the entire extent of the medial hard palate.
 - Judicious use of needlepoint diathermy on low setting can help to elevate firmly attached areas that are not easily released with the Mitchell's trimmer.
- Once the edge of the nasal mucoperiosteal flap is defined, slide the trimmer around the corner of the hard palate onto the nasal surface of the bone staying right on bone. If the edge is sufficiently liberated, then sweep anteriorly and posteriorly to liberate the entire sheet off of the nasal surface (**TECH FIG 4A**).
 - If a portion of the edge is still attached, resist further sweeping until releasing the portion that remains tethered to prevent a tear.
- This dissection is continued to the posterior nasal spine. At this juncture, there are always muscle attachments. Release these aberrant velar muscle attachments with needlepoint diathermy.
- Continue dissection along the nasal surface following the posterior edge of

the bone cephalad and lateral toward the medial surface of the medial pterygoid plate (**TECH FIG 4B**).

- Release the nasal mucoperiosteum directly off the bony surface of the medial surface of the medial pterygoid plate with careful dissection of the fibrous attachments here. Be patient and careful during the release of this densely adherent portion of the nasal mucosa working posteriorly and cephalad along the pterygoid plate and palatine bone. Confirm complete release by directly visualizing the plane of the medial surface of the medial pterygoid plate. If further release is required, the origin of the tensor veli palatini (TVP) along the medial pterygoid plate may be severed to improve mobilization.
- The sheet of mucosa should now be freely mobile as one continuous sheet posteriorly and along the anterior medial hard palate. When extensive dissection is required for a wide cleft, there may be a noticeable reduction in the circumference of the oropharynx as the sheet mobilizes medially.

TECH FIG 4 • A. Elevation of nasal mucoperiosteal flaps. **B.** Nasal flap dissection toward the medial surface of the medial pterygoid plate.

- Attention is then turned to the greater segment.

- The dissection of the nasal mucoperiosteal flap is identical posteriorly along the hard palate cleft margin.
- Anteriorly, at the bony junction of the vomer and bony palate, the nasal mucoperiosteum is raised in continuity with the vomerine periosteum.
- This vomerine flap is raised cephalad directly off bone and in continuity with the periosteum of the nasal surface of the hard palate.

Nasal Closure

- Nasal layer closure is then commenced once there is assurance that the repair is tension free by checking that both sides are sufficiently liberated.
- Meticulous closure with knots tied on the nasal side
- Small wedges are excised out at the base of the oral surface of the uvula to assist closure. Place eversion sutures during the closure of the uvuli to prevent notching or bifidity.

Dissection and Reconstruction of the Velar Musculature

- With the nasal layer completely closed, proceed with the muscle dissection and reconstruction of the velopharyngeal sphincter.
 - Three steps are critical for muscle repositioning:³
 - Identification and separation of levator veli palatini (LVP)
 - Velar musculature dissection and release from its attachments to the cleft margin and hard palate shelf
 - Velar musculature repositioning and repair
 - Deep to the muscles inserted into the back of the bony hard palate, the LVP inserts abnormally at the cleft margin in the anterior half of the velum.
- Using a scalpel, sharply dissect the velar muscle layer off of the nasal mucosa along the cleft margin. This is done with a paramedian incision lateral to the nasal mucosal closure line through muscle until the nasal mucosal surface is identified.
 - It is easiest to separate the muscle layer once the nasal mucosa has been repaired to give a “trampoline” effect, providing tactile feedback and countertraction during this careful dissection.
 - Also, it is important to note that the bulk and breadth of the muscle widen as you dissect laterally. This is analogous to the changing depth of a swimming pool, with a shallow end (paramedian) becoming deeper as one progressively dissects laterally.
- The velar musculature is raised off the nasal mucosa and separated from the

tendinous fibers of the TVP. This separation is done laterally along the hard palate shelf at the junction of “salmon pink” velar muscle fibers and tendinous fibers of the TVP.

- The velar musculature is further dissected until it can be freely mobilized to lie parallel to the posterior hard palate margin and overlying the contralateral velar muscle bundle.
- You have completed the levator dissection when the “salmon pink”-colored longitudinal fibers of the levator are identified emerging from the skull base and the entire dissected muscle is free to be reoriented to a more functionally effective position in the posterior half of the soft palate.
- The dissection of the velar musculature is performed on both sides.
- Repair the muscles and reconstruct the levator muscular sling by suturing the muscles and securing with multiple sutures, knots facing the nasal surface.
- Ensure proper hemostasis is achieved.

Oral Closure

- Close the oral layer beginning with stay sutures placed anteriorly and progressing posteriorly toward the uvuli with horizontal mattress sutures.
 - There is no attempt of push-back of the flaps for lengthening with a V-Y closure.
- During oral layer closure, place some full-thickness sutures through both the oral and nasal layers just posterior to the hard palate shelf (anterior to muscle repair) to help obliterate the dead space and position the muscle repair.
- Place interrupted simple sutures between each of the mattress sutures.
- Attempt to minimize raw bone exposure by closing palatal flaps to alveolus wherever possible.
- Recheck for adequate hemostasis, irrigate, and remove throat pack.
- If concerned for airway during postoperative period, consider nasopharyngeal tube insertion and a tongue stitch.

■ Two-Flap Palatoplasty—Bilateral Complete Cleft Palate

- In a bilateral cleft palate, the operative steps are similar to those outlined above except for the flap elevation and closure anteriorly along the junction of the primary and secondary palate.

- The oral and mucosal nasal incisions and dissections on the lesser segment are performed as outlined above.
- Bilateral vomerine flaps are raised from the premaxilla in continuity with the nasal mucoperiosteal flaps (**TECH FIG 5**).
- The anterior closure of the nasal and oral layers requires meticulous approximation and closure to eliminate the risk of an oronasal fistula at the junction of the primary and secondary palate.
- Careful and patient dissection is required to the dense attachments of mucoperiosteum to the posterior surface of the premaxilla to which the palatal flaps will be anchored.

TECH FIG 5 • Markings of a two-flap palatoplasty for a bilateral complete cleft palate.

Headlight and positioning	■ Good lighting and access paramount importance
Loupe magnification	■ Especially helpful for dissection around palatine foramina and muscle when surgeon is less experienced
Hemostasis	■ Ensure meticulous hemostasis throughout case to optimize visualization. ■ Judicious use of needlepoint diathermy ■ Failure to do so may result in airway compromise, flap necrosis, and wound dehiscence.
Use needlepoint diathermy to make hard palate incisions.	■ Controls bleeding and persisting ooze
Work on broad front.	■ Avoid tunneling during dissection.
Patience and precision during dissection especially around palatine foramina	■ Bleeding obscures view, and careless dissection risks injury to pedicle and vascularity of the flap.
Handle tissues with care.	■ Nasal mucosa is especially susceptible to tears.
Inset palatal flaps with stay sutures to help control closure.	■ Helps to put the most difficult sutures anteriorly with stay sutures to judge closure and maintains good exposure
Do not attempt closure until all layers are sufficiently mobilized.	■ Prevents tearing ■ If sutures are prematurely placed, further attempts to mobilize tissue are more likely to result in tears. Prematurely suturing may also result in tears if tension is still present.
Oronasal fistula	■ Critical to achieve adequate tissue dissection, perfect approximation, and apposition of tissue layers with meticulous suture technique to prevent fistulae.

POSTOPERATIVE CARE

- Nasopharyngeal tube as required

- Remove tongue stitch in recovery if used.
- Analgesia to reduce blood pressure and distress (24 hours of intravenous opioids)
- Encourage feeding.
- Postoperative visit in 4 weeks

OUTCOMES

- Two-flap palatoplasty yields excellent speech outcomes with minimal surgical morbidity.
- In a 20-year long-term follow-up, the authors have recorded a 7% to 11% incidence of velopharyngeal insufficiency with no significant difference between cleft subtypes.⁴
- Speech results were normal to mildly impaired resonance (92%), no or inaudible nasal air emission (80%), and no compensatory articulation errors (98%).
- The fistula rate of a cleft palate repair with a unipedicled flap technique is 6.2% (95% CI, 4.3%–8.4%) according to a systematic review of international data.⁵
- The effect of palatoplasty on maxillary facial retrusion is controversial. Inherent maxillary growth deficiency, secondary scarring from palatal flap elevation, and timing of repair are all contributing factors to midfacial retrusion.⁶ Deleterious growth has been shown to be greatest in patients treated by Veau push-back technique. Further long-term studies are required to compare the effect of palatal flap technique on maxillary growth restriction.

COMPLICATIONS

- Bleeding is a feared complication as it may lead to an emergency with airway obstruction and respiratory compromise. Additionally, hematoma may lead to compression of the pedicle or flap, with resultant flap necrosis, wound dehiscence, and oronasal fistulae. To prevent this complication, vigilant hemostasis is an absolute and adequate postoperative analgesia is necessary.
- Airway obstruction may occur in the absence of hemorrhage, and a tongue stitch or nasopharyngeal tube may assist in prevention of obstruction in infants at risk. Airway obstruction can also occur if a throat pack is utilized and the surgeon overlooks removal of the throat pack prior to extubation.
- Flap necrosis is rare and avoidable with careful dissection and release of the periosteal sleeve of the greater palatine pedicle.

- Infection and wound dehiscence leading to oronasal fistulae are detrimental. A small fistula secondary to delayed wound healing may heal with conservative measures. Failure of closure may necessitate reoperation with re-elevation and closure of oral and nasal flaps as well as possible augmentation using local flaps and/or biologic adjuncts.

12 CHAPTER Tongue-Lip Adhesion/Floor of Mouth Muscle Release for Pierre Robin Sequence

Chad A. Purnell and Arun K. Gosain

DEFINITION

- Pierre Robin sequence (PRS) is a clinical triad of glossoptosis, retrognathia, and airway obstruction.
- Cleft palate is present in approximately 50% of cases.
- PRS is associated with an identified syndrome in 30% to 60% of cases.¹
- The most common syndromes associated with PRS are Stickler syndrome (11%–20%) and 22q11.2 deletion (velocardiofacial) syndrome (11%).²

ANATOMY

- The tongue in PRS is posteriorly displaced due to retrognathia. This results in an airway obstruction at the tongue base (**FIG 1**).
- Airway obstruction may also result from lesions lower than the tongue, such as laryngomalacia. Synchronous airway lesions are present in up to 28% of patients.³
- Cleft palate may be U- or V-shaped; a U-shaped palatal cleft is classically associated with PRS.

PATHOGENESIS

- Pathogenesis of PRS is incompletely understood and likely multifactorial.

FIG 1 • Micrognathia results in a more posterior position of the mandible and tongue in PRS (*solid lines*) compared to a normal patient (*dotted lines*).

- Theorized mechanisms of PRS include mechanical obstruction to mandibular growth, delay in neuromuscular development of the tongue and oropharynx, connective tissue dysplasia, and teratogen exposure.^{4,5}

NATURAL HISTORY

- PRS occurs on a spectrum that ranges from mild asymptomatic hypoplasia to critical airway obstruction requiring emergent endotracheal intubation at birth.
- In more severe phenotypes, PRS is often associated with feeding issues such as gastroesophageal reflux, failure to thrive, and abnormal oroesophageal motility.^{6,7}
- Mortality has decreased dramatically with improved awareness and care. Mortality in 1946 was greater than 50% and has decreased to 16%, with all deaths occurring in syndromic patients.^{8,9}

PATIENT HISTORY AND PHYSICAL FINDINGS

- A full birth history and physical examination should be performed. A key point of examination should be documenting the maxillomandibular discrepancy with the child upright and the mandible closed.
- A careful examination for syndromic features should include hearing and ocular exam to evaluate for Stickler syndrome.¹⁰
- Evaluation and treatment of any patient with PRS should be performed by a multidisciplinary team, which includes craniofacial surgery, otolaryngology, speech and feeding therapy, critical care/anesthesiology, and genetics.

IMAGING

- If the child is not intubated, a polysomnogram should be performed, including a portion with a nasopharyngeal airway in place in order to determine whether there is ongoing sleep apnea if upper airway obstruction is removed.
- Fiberoptic nasendoscopy is performed to evaluate whether the airway obstruction is isolated to the tongue base or whether there are additional sources of supraglottic airway obstruction, including laryngomalacia.
- Prior to any surgical intervention, bronchoscopy should be performed to evaluate for subglottic synchronous airway lesions.

NONOPERATIVE MANAGEMENT

- The majority of patients can be treated nonoperatively.
- Initial airway management is prone positioning to displace the mandible anteriorly.
- Supplemental oxygen may be added as well.
- A nasopharyngeal airway should be placed if desaturations continue. This airway has been utilized successfully as end-treatment at home by several centers.¹¹
- If a nasopharyngeal airway does not resolve airway obstruction, emergent endotracheal intubation is indicated.
- Continuous positive airway pressure masks and palatal appliances have also been described for treatment.^{12,13}

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to any surgical treatment, bronchoscopy should be performed. In the

presence of significant subglottic obstruction, tracheostomy is likely the only treatment option.

- Prior to performing a tongue-lip adhesion, a GILLS score should be calculated. One point is given for each of the following: gastroesophageal reflux, intubation preoperatively, late operation (greater than 2 weeks of age), low birth weight (less than 2500 g), and syndromic diagnosis. A score of 3 or more is predictive of failure of tongue-lip adhesion, and another option such as mandibular distraction osteogenesis or tracheostomy should be considered.^{14,15}

Positioning

- The procedure is performed supine.
- Endotracheal intubation may be nasotracheal or orotracheal, with the tube taped to the side out of the operative field.

Approach

- Soft tissue procedures for PRS include tongue-lip adhesion, subperiosteal release of the floor of mouth, or both procedures performed concomitantly.^{16,17}
- Subperiosteal release of the floor of mouth is an ideal addition to tongue-lip adhesion if the patient has a fixed, immobile tongue (ankyloglossia) and a tongue-based airway obstruction. This procedure is also performed in isolation for airway obstruction at some centers.
- Mandibular distraction osteogenesis is a skeletal technique to treat mandibular hypoplasia that may have more repeatable resolution of airway obstruction in a broader range of patients with PRS, with potentially higher complication rates.^{18–20}

TECHNIQUES

Video p8-c012

■ Subperiosteal Release of the Floor of the Mouth

Creation of Tongue and Lip Flaps

- 0.5% lidocaine with epinephrine is injected into all planned incisions for hemostasis.
- A transverse incision is made 1.5 cm in length in the lower lip (**TECH FIG 1A**).
 - Incision is carried obliquely posterior into the muscle of the lip to create a superiorly based flap approximately 1.5×1 cm in area.
- A 1.5-cm transverse incision is made in the undersurface of the tongue approximately 2 mm inferior to the rugae (**TECH FIG 1B**).
- An inferiorly based 1.5- $\times$ 1-cm musculomucosal flap is elevated (**TECH FIG 1C**).

TECH FIG 1 • A. A 1.5- × 1-cm flap is marked in the mucosa of the inferior lip. **B.** A 1.5- ×1-cm inferiorly based flap is marked on the inferior tongue. **C.** See **TECH FIG 4.** Tongue musculomucosal flap after elevation.

TECH FIG 2 • A. A V-shaped incision is placed on either side of the tongue frenulum for subperiosteal release of the tongue. **B.** Area of periosteal elevation of the lingual surface of the mandible.

Subperiosteal Release of the Floor of the Mouth

- A separate V-shaped incision is made around the base of the frenulum of the tongue (**TECH FIG 2A**).
- Dissection is carried anteriorly until the lingual surface of the mandible is reached. The periosteum of the mandible is incised.
- A periosteal elevator is used to completely elevate the periosteum of the lingual surface of the symphysis, parasymphyses, and bilateral mandible bodies (**TECH FIG 2B**).
- Incision is closed in a V-to-Y advancement fashion with 4-0 Vicryl in the muscle layer and 5-0 Monocryl for the mucosal layer.

Placement of Tongue Suspension Suture

- A loop of 4-0 silk suture is tied through one hole of a surgical button and left

long as an emergency pullout suture.

- The button is placed on a backer of adhesive foam to help prevent pressure sores (**TECH FIG 3A**).
- 2-0 polypropylene suture on a long, curved taper needle (2-0 Prolene on a CT-1 needle; Ethicon, Somerville, NJ) is used after straightening the needle slightly to allow the needle to capture the anterior tongue mass.
 - This suture is passed through the raw area created by the tongue flap, through the mass of the anterior tongue musculature, and out the posterior tongue mucosa at a point where the tongue starts to curve toward the oropharynx in a more vertical orientation.
 - The needle is then passed through the button, then back through the tongue in a mattress fashion (**TECH FIG 3B**).
- The suspension suture is pulled forward to assess anterior movement of the tongue mass as the suture is brought under tension.
- If tongue movement is acceptable, the suture is brought through the incision in the lower labial sulcus, staying anterior to the mandible, to exit the skin in a submandibular crease.
 - The loose end of the suture can be threaded through a Keith needle and passed parallel to the first end to complete the mattress suture.
- Before removing the needles, both suture ends are passed through a foam-backed button, over which the suture will be tied. Foam should be firm and can be fashioned from the foam backing within an empty needle pack.
 - The button overlying the tongue mass does not require foam backing, whereas the submandibular button does require foam backing to avoid ulceration of the facial skin.

Closure and Tensioning of Tongue

- The posterior mucosa of the tongue is approximated to the inferior aspect of the labial sulcus incision using interrupted 5-0 Monocryl suture (Ethicon, Somerville, NJ).
 - Sutures are placed sequentially from one side of the incision to the other, taking care to place the knots such that they lie on the mucosal side of the closure (**TECH FIG 4A**).

TECH FIG 3 • A. A backer of adhesive foam is placed on the back of the surgical buttons to prevent pressure sores from the buttons. **B.** Path of 2-0 polypropylene suspension suture through the tongue and surgical button and out the skin.

- The muscle of the tongue and the lip are approximated on either side and in the center of the limbs of the suspension suture using 4-0 Vicryl suture (Ethicon, Somerville, NJ). Three such sutures are usually sufficient.
- The anterior mucosa of the tongue is approximated to the superior aspect of the labial sulcus incision using interrupted 5-0 Monocryl suture. Sutures are placed sequentially from one side of the incision to the other, taking care to place the knots such that they lie on the mucosal side of the closure.
- Tension on the tongue suspension suture is determined by gently securing the first knot over the submandibular foam-backed button until the tongue mass just begins to move forward. No further tension should be placed so as to minimize pressure on the skin. Subsequent knots are placed to secure the suture (**TECH FIG 4B**).
- The purpose of the suspension suture is simply to take pressure off of the mucosal and muscular layers of the closure for the first 7 to 10 days, and sequelae such as tongue edema or skin ulceration can be minimized by placing the least amount of tension on the suture required to move the tongue mass forward.

- The safety silk suture tied to the button in the mouth is taped to the cheek.
- A nasogastric tube is placed to facilitate feeding.

TECH FIG 4 • A. Posterior layer of mucosal flaps is closed with 5-0 Monocryl sutures. **B.** Suspension suture is tied over a button under the chin. Note the safety silk suture used to retrieve the intraoral button.

PEARLS AND PITFALLS

Preoperative screening

- Nasendoscopy and bronchoscopy are essential prior to tongue-lip adhesion. The procedure should not be performed if there are any synchronous airway lesions.

Suspension suture

- The suspension suture should be tensioned to pull the base of the tongue forward but should not be pulled maximally as to cause tissue necrosis and increased tongue edema.

Postoperative care

- The adhesion should NOT be left in place until repair of cleft palate. This jeopardizes oromotor development and mobility of the tongue.

POSTOPERATIVE CARE

- Extubation is carried out when deemed appropriate by anesthesiology or critical care. A nasopharyngeal airway is left in place for several days to manage the airway while surgical edema is present.

- The suspension suture is left in place for 7 to 10 days.
- The child is monitored carefully for resolution of airway obstruction. Postoperative polysomnography is performed.
- If airway obstruction resolves, the patient is evaluated every 1 to 2 months. The tongue is monitored for active motion in response to touch, a sign of maturing tongue function.
- If tongue motion has matured and MMD has decreased to 3 mm or less, the adhesion is taken down, usually by 6 to 7 months of age.
- Early takedown of the tongue-lip adhesion is preferable so as to avoid oromotor delay in tongue function. Prior reports left the adhesion in place until the time of palate repair, often close to or later than 1 year of age. We believe that this can contribute to oromotor retardation. In addition, it is preferable to take down the tongue-lip adhesion well before the palate repair so as to assess adequacy of airway prior to further airway restriction that accompanies cleft palate repair.

OUTCOMES

- Resolution of airway obstruction is variable in studies of tongue-lip adhesion, ranging from 43% to 89%.^{15,21}
- Complete resolution of feeding difficulties also is variable, but many authors report an approximately 60% rate of ability to oral feed without any tube-feeding supplementation. Variabilities may exist due to institution-based protocols for surgical feeding tube placement.^{22,23}
- Few studies comprehensively assess polysomnographic findings after tongue-lip adhesion. Sedaghat et al.²⁴ describe improvement in sleep study findings in 7/8 patients after adhesion, but only 3 patients had reduction to mild or no sleep apnea. Flores et al.¹⁸ describe improvement in apnea-hypopnea index in 15 patients after adhesion, but improvement was significantly less compared to mandibular distraction patients.
- Tongue-lip adhesion has minimal effects on long-term speech development.²⁵

COMPLICATIONS

- Dehiscence (greatly reduced in techniques that utilize a suspension suture)
- Failure to completely resolve airway obstruction
 - In these cases, the airway should be reassessed for sites of synchronous airway lesions that may not have been appreciated, paying particular attention to supraglottic airway compromise and laryngomalacia.

- If the only other site of airway compromise is some element of laryngomalacia, the multidisciplinary team should be consulted regarding potential role for mandibular distraction osteogenesis with or without supraglottoplasty.
- If the patient is found to have laryngomalacia and is not felt to be a candidate for mandibular distraction osteogenesis with or without supraglottoplasty, or if synchronous subglottic airway compromise is identified (eg, tracheomalacia), then tracheostomy is recommended.
- Requirement for prolonged nasogastric feeds or gastrostomy tube

CHAPTER Palatal Fistula

Gregory D. Pearson

DEFINITION

- A fistula is defined as an epithelialized tract between two cavities that are not meant to be communicating.
- A palatal fistula is an abnormal communication between the oral and nasal cavities.
- Palatal fistula can be intentional or unintentional.
 - Intentional fistulas are fistulas not repaired at the time of initial operation. Examples include:
 - The alveolar cleft with a Veau III or Veau IV (unless the surgeon elects to perform a gingivoperiosteoplasty)
 - A Veau IV with a “locked out” premaxilla
 - Unintentional fistula after palatoplasty^{1–3}:
 - These fistulas are unwanted and not planned for during the initial operation.
 - Veau IV clefts are associated with the highest fistula rate.
 - No difference in risk for palatal fistula related to gender, age at time of repair, and race.
 - The difference in fistula rate between straight line repairs and Furlow-type repairs appears to be surgeon/institution dependent with no clear lower risk between the two types of repair.
- Palatal fistula repair can be an extremely challenging problem to solve and prevention is the best option.

ANATOMY

- The Pittsburgh fistula classification system classifies fistulas as I to VII, from

a posterior to anterior location on the palate⁴ (**FIG 1**).

- Type I involves only the uvula (consisting of a bifid uvula).
- Type II involves the soft palate.
- Type III occurs at the junction of the hard/soft palate.
- Type IV arises within the hard palate.

FIG 1 • Pittsburgh fistula classification system.

- Type V is located at the incisive foramen (reserved for Veau IV clefts).
- Type VI is a lingual alveolar communication on the alveolus.
- Type VII is located on the labial side of the alveolus.

PATHOGENESIS

- Occurrence rates of palatal fistula vary from 0% to 60% in reported literature.¹⁻³
- Several factors have been associated with the prevention of palatal fistula:
 - Tension-free and watertight closure
 - Relaxing incisions advocated by von Langenbeck for tension-free closure.
 - Jackson et al. proposed “CHOP modification” of Furlow palatoplasty for soft palate repair.²
 - Complete two-layer closure of nasal and oral flaps
 - LaRossa promoted liberal use of vomer flaps for closure of the nasal floor.⁵
 - Infection prevention
 - The use of perioperative antibiotics is debated in the literature.

NATURAL HISTORY

- Palatal fistula will remain patent until the time of closure.
- A fistula can be symptomatic or asymptomatic

PATIENT HISTORY AND PHYSICAL FINDINGS

- Palatal fistula can occur after cleft palate repair, oncologic resection, trauma, or illicit drug use.
- Patients may report that the fistula is symptomatic.
 - Nasal escape of food or liquids
 - May be intermittent
 - Typically, viscous liquids like yogurt
 - Nasal escape of air
 - May be noted by patient as change in voice
- May be noted by speech pathologist as nasal turbulence or hypernasality
- Physical examination will demonstrate a hole or communication from the oral to nasal cavity.
 - Fistulas can range from small to large and vary in location on the palate.
 - Small fistulas can be difficult to see, but the patient can typically state/point to the location.
 - An examination under anesthesia with a lacrimal probe can be useful to determine the location, size, and orientation of a fistula.
 - A dental mirror can be useful in evaluating anterior fistulas.
 - Deep crevasses or folds of mucoperiosteal tissue can simulate a fistula.
 - Palatal expansion may open an occult fistula that was already present.

IMAGING

- Radiographic fistulograms (such as those performed for an enterocutaneous fistula evaluation) are not necessary.
- Physical examination should determine whether a fistula is present.
- Nasopharyngoscopy or video fluoroscopy should be employed to determine velopharyngeal gap size in patients with fistula and velopharyngeal dysfunction.

DIFFERENTIAL DIAGNOSIS

- Hypernasality from velopharyngeal dysfunction (VPD)
- Nasal escape of liquids/food secondary to poor oral motor planning/retrograde

oronasal reflux

NONOPERATIVE MANAGEMENT

- Obturators/dental retainers can be fabricated by dentists or orthodontists to provide symptomatic relief (**FIG 2**).
- Obtaining patient compliance for wearing the retainer can be difficult.
- The dental brackets on the retainer may loosen and require retightening or fabrication of a new splint.
- The patient must have enough teeth to properly support a retainer.

SURGICAL MANAGEMENT

- Surgical management and operative options are largely dictated by the location of the palatal fistula based upon the Pittsburgh classification system.
- When determining whether to repair a fistula, the surgeon should strongly consider and assess whether the fistula is symptomatic.
 - Nasal escape of fluids or foods, hypernasality, and preventing further surgical or orthodontic interventions (eg, bone grafting or orthognathic surgery) are all reasons for attempted fistula repair.
- Pittsburgh type I
 - Bifid uvula rate ranges from 1.34% to 19% of selected populations, but the true fistula rate is probably underestimated in the literature.
 - Because these fistulas tend to be asymptomatic as well as concerns about anesthesia on pediatric brain development, these fistulas are the least likely to be repaired as a primary objective for an operation.
- Pittsburgh type II
 - When determining the type of reconstruction choice for a soft palatal fistula repair, a surgeon should also make a determination related to a child's resonance (specifically if VPD is present) and the type of previous repair performed.
 - If the child has VPD, the fistula may be fixed but hypernasality will likely persist unless addressed with the repair.
 - If a child has normal resonance regardless of the type of primary palatoplasty performed, augmentation/reinforcement with acellular dermal matrix (ADM) can be used.⁶
 - For patients with a fistula after straight-line repair and concurrent VPD, addressing the VPD with either a palatal lengthening procedure or VPD surgery should be strongly considered.

- A conversion to a Furlow double opposing Z-plasty typically allows repair of a type II fistula while addressing VPD in children with small velopharyngeal gaps on imaging.⁷
- The CHOP modification with bilateral relaxing incisions can facilitate tension-free closure.
- For larger velopharyngeal gaps and fistula or very large fistula (dehiscence), a superiorly based posterior pharyngeal flap may be necessary as conversion to Furlow may not lengthen the palate sufficiently.
- Pittsburgh type III
 - Traditional teaching reports that the junction of the hard palate and soft palate remains the most common site of fistula, particularly when employing a Furlow palatoplasty.
 - As for type II fistula, the patient's resonance and type of previous repair should influence the operation considered for fistula repair.
- Pittsburgh type IV
 - There is significant overlap for techniques used to repair type III and IV palatal fistulas.
 - The mucoperiosteal flaps tend to scar, become stiffer, and have less mobility compared to flaps used in a primary palatoplasty, thus limiting their advancement or rotation potential.
- Pittsburgh type V
 - This is the second most common location of fistula as well as the most challenging to repair given the relative lack of palatal tissue in this area.
 - These fistulas are often the result of either poor inset of the lateral palatal mucoperiosteal flaps into the premaxillary segment or more commonly a premaxillary segment that is so anteriorly displaced out of the arch (a "locked out" premaxilla and intentional fistula) that closure at the time of initial palatoplasty is not possible.

FIG 2 • Palatal fistula **(A)** covered with an obturator **(B)**.

- Pittsburgh type VI and VII fistulas pertain to the alveolar arch and labial sulcus and are addressed in the chapter on alveolar cleft repair.

Preoperative Planning

- The surgeon must discuss the possibility of palatal fistula recurrence after attempted closure with the patient and family.
- Assuring proper patient compliance with postoperative instructions prior to embarking upon repair is imperative.
- Depending on the type of repair technique used, a surgeon may consider having orthodontist fashion of a postsurgical retainer to protect repair while healing, particularly for type IV and V fistulas.
 - It is important to ensure the retainer does not put pressure on flaps or area of repair while still protecting the surgical site from tongue and food particulate.
- As previously stated, in rare instances, an examination under anesthesia with a lacrimal probe can be useful to determine the location, size, and orientation of a fistula.
- If a local flap is used, it must be protected from masticatory trauma during healing.

Positioning

- The patient should be orally intubated.
 - May use a regular endotracheal tube or oral RAE endotracheal tube depending upon surgeon and anesthesiologist's preferences.
 - The endotracheal tube may be positioned in the midline or laterally depending on the repair technique chosen.

- Typically, the patient should be placed in a horseshoe headrest with a shoulder roll and slight extension of the neck.
- A Dingman mouth prop or dental bite blocks (in which use depends on surgical technique to be employed) can be extremely useful for proper exposure of the intraoral cavity.

Approach

- Although multiple strategies can be performed for each site, the most common/useful approaches will be addressed according to the Pittsburgh classification system.
- Pittsburgh type I: Excision and reapproximation
- Pittsburgh type II:
 - Lateral relaxing incisions and rerepair
 - May consider augmentation with ADM
 - Conversion by Furlow palatoplasty
 - Posterior pharyngeal flap
- Pittsburgh type III:
 - Lateral relaxing incisions and rerepair
 - May consider augmentation with ADM
 - Posterior pharyngeal flap (if VPD present)
 - Buccal myomucosal flap
 - Facial artery musculomucosal (FAMM) flap
- Pittsburgh type IV:
 - Lateral relaxing incisions and rerepair with pushback technique
 - May consider augmentation with ADM
 - Elevation of mucoperiosteal flaps and pushback technique
 - Labial mucosal flap
 - If space in dental arch to pass through or if bite blocks employed
 - Buccal myomucosal flap
 - FAMM flap
 - Tongue flap
 - Free tissue transfer
- Pittsburgh type V:
 - Labial mucosal flap
 - FAMM flap
 - Tongue flap

- Premaxillary turnover flap
 - Primarily used as nasal lining flap for fistula at anterior incisive foramen in Veau IV cleft
- Free tissue transfer

TECHNIQUES

■ Excision and Reapproximation

- Midline oral endotracheal tube placement; head placed in headrest with slight extension.
- Perform proper surgical time-out.
- Place Dingman mouth prop.
- Prep and drape the patient.
- Mark out medial epithelialized areas that must be excised.
- Inject with local anesthesia of choice. Author prefers ¼% Marcaine with 1:200 000 epinephrine.
- Excise medial portions of fistula.
- Repair with resorbable sutures. Author prefers 4-0 chromic sutures.

■ Lateral Relaxing Incisions and Rerepair (TECH FIG 1)

Preparation for All Fistula Types

- Midline oral endotracheal tube placement; head placed in headrest with slight extension.
- Perform proper surgical time-out.
- Place Dingman mouth prop.
- Prep and drape the patient.
- Mark out lateral relaxing incisions (von Langenbeck style relaxing incision on the hard palate, soft palate, or both depending upon fistula type).
 - Relaxing incisions typically need to be longer than initially thought due to relative immobility of soft tissues.
- Inject with local anesthesia of choice. Author prefers ¼% Marcaine with

1:200 000 epinephrine.

Pittsburgh Type II Fistula

- Incise lateral relaxing incisions on the soft palate.
- Incise medial fistula.
- Separate nasal mucosa from levator muscles with sharp dissecting scissors.
- Separate oral mucosa from levator muscles with sharp dissecting scissors.

TECH FIG 1 • A. Lateral relaxing incisions. B. Rerepair.

- Make certain that levator muscles are not tethered to the hard palate, if so release sharply.
- Repair nasal mucosa with interrupted, buried (knot on nasal side) sutures. Author prefers 4-0 chromic.
- Repair levator musculature with re-establishment of levator sling. Author prefers 4-0 Monocryl.
- Repair oral mucosa with interrupted sutures. Author prefers 4-0 chromic.
- If augmenting closure with ADM, after muscle repair, place a thin piece of ADM over muscle with ample coverage beyond suture line. Author uses double-armed 4-0 Monocryl sutures suturing from underneath ADM through oral mucosa allowing knots to easily be placed and tied on oral mucosal side.
- Place tongue stitch and remove Dingman device.

Pittsburgh Type III Fistula

- Incise lateral relaxing incisions on the hard and soft palate.
- Incise medial fistula.
 - It is typically easier to recruit oral mucosa compared to nasal mucosa, so the initial markings should be slightly on the more lateral portions of the fistula to allow easier closure of the nasal mucosa.
- Use Joseph Periosteal Elevator to elevate mucoperiosteal flaps from the hard palate with care taken to preserve greater palatine vessels.
- Release soft palate lateral relaxing incision from hamulus and junction of the hard palate/end of alveolar ridge.

- Dean scissors can be a useful instrument to release medial tissue off hamulus.
- Separate nasal mucosa from levator muscles (if present) and release nasal mucosa from nasal side of the hard palate.
- Separate oral mucosa from levator muscles with sharp dissecting scissors (if present).
- Make certain that levator muscles are not tethered to the hard palate, if so release sharply.
- Repair nasal mucosa with interrupted, buried (knot on nasal side) sutures.
- Repair levator musculature with re-establishment of levator sling (if previously released).
- Place liberal ADM prior to closure of oral mucosal flaps.
- Repair oral mucosa with interrupted sutures.
- Ensure hemostasis of lateral relaxing incisions.
- Place tongue stitch and remove Dingman.

Pittsburgh Type IV Fistula

- Incise lateral relaxing incisions on the hard and soft palate (if necessary depending on location of fistula in hard palate).
- Incise medial fistula.
 - It is typically easier to recruit oral mucosa compared to nasal mucosa, so the initial markings should be slightly on the more lateral portions of the fistula for easier closure of the nasal mucosa.
- Use Joseph Periosteal Elevator to elevate mucoperiosteal flaps from the hard palate with care taken to preserve the greater palatine vessels.
 - Determine whether fistula is too large for closure and if pushback technique will be required.
 - If pushback is required, continue lateral relaxing incisions more proximally, depending upon the location of fistula either incise from medial portion of fistula toward alveolus or fashion-like Veau-Wardill-Kilner-type palatoplasty.
- Separate/release nasal mucosa from nasal side of hard palate to allow medial mobilization.
 - A double hockey or Pigtail instrument or Woodson can be extremely helpful for this dissection.
- Repair nasal mucosa with interrupted, buried (knot on nasal side) sutures.

- Place liberal ADM prior to closure of oral mucosal flaps.
 - Repair oral mucosa with interrupted sutures.
 - Resuspend flaps to lateral relaxing incisions without placing undue tension on medial repair.
 - Ensure hemostasis of lateral relaxing incisions.
 - Place tongue stitch and remove the Dingman device.
-

■ Conversion by Furlow Palatoplasty

- Refer to Chapter on Furlow Palatoplasty (Chapter 8), for description of this technique.
 - The CHOP modification should be encouraged if any concerns for tension on repair exist.
-

■ Posterior Pharyngeal Flap

- Please see chapter on Velopharyngeal Insufficiency (Chapter 14) for description of this technique.
 - A palatal split technique (as described by Owsley⁸) should be considered over a fish-mouth technique as described by Argamaso.⁹
-

■ Labial Mucosal Flap

- Must be able to protect this flap from masticatory trauma by either having space to pass through dental arch or by having temporary bite blocks placed on the teeth.
- Midline oral endotracheal tube placement; head placed in headrest with slight extension.
- Perform proper surgical time-out.
- Placement of Dingman mouth prop.
- Prep and drape the patient.
- Mark out medial portions of the fistula.
 - Recruit tissue from oral side as previously described.
- Mark out flap on labial wet vermillion (this is a hinge- or finger-type flap).
 - The base of flap and point of rotation of flap can be unipedicle or bipedicle

depending upon the location of fistula and Veau-type cleft.

- Typically for Veau III clefts with recruitment of tissue from posterior segment.
- Make certain to place incision line several millimeters above the attached gingiva so that closure of donor defect is made easier.
- Inject with local anesthesia of choice. Author prefers ¼% Marcaine with 1:200 000 epinephrine.
- Incise and repair medial portions of fistula as previously described.
- Incise buccal flap and elevate with sharp scissors.
 - Elevate this flap off the orbicularis muscle to maintain as much blood supply because this is a random pattern flap.
- Rotate flap into defect.
- Sew flap to raw oral mucosal edges (preferably through dental arch defect) (**TECH FIG 2**).
- Close donor defect with interrupted sutures.
- Place tongue stitch and remove Dingman device.

TECH FIG 2 • Design of a labial mucosal flap.

■ Buccal Myomucosal Flap

- Oral endotracheal tube placement; head placed in headrest with slight extension.
- Perform proper surgical time-out.
- Prep and drape the patient.
- Place Dingman mouth prop or dental mouth prop.

- Place several retraction sutures on the lip to aid in retraction/visualization.
- Identify Stensen duct.
 - The flap is caudal to the duct.
- Mark out flap from area over ascending ramus transversely oriented to oral commissure (stay on wet vermilion) (**TECH FIG 3A,B**).
 - The base of flap is about 1.5 cm.
 - Narrow the flap distally.
- Inject with local anesthetic.
- Incise mucosa and sharply dissect from the distal end of flap toward base of flap (**TECH FIG 3C**).

TECH FIG 3 • **A.** Design of a buccal myomucosal flap. **B.** Markings. **C.** Flap elevation. **D.** Flap inset into a palatal defect. **E.** Division of base of flap.

- A portion of the buccinator muscle is taken to improve the vascularity of the flap (as described by Mann,³ this is an intramuscular dissection).
- This flap can be elevated bilaterally if needed.
- Prepare fistula site so that some nasal mucosa can be rolled in (complete nasal mucosa closure is not critical).
- Make certain to elevate raw edges of oral mucoperiosteal tissue to inset the

flap.

- Rotate flap into defect and sew in place attaining excellent approximation of mucosal edges (**TECH FIG 3D**).
 - Flap will need to be rotated posteriorly behind dental arch or through space in dental arch that can be protected from masticatory trauma (can use oral splints on teeth as well).
 - Close donor site in a single layer.
 - Place tongue stitch and remove Dingman/dental mouth prop.
 - The base of this flap may be subsequently divided after 3 to 4 weeks (**TECH FIG 3E**).
-

■ Facial Artery Musculomucosal Flap¹⁰

- Oral endotracheal tube placement, place head in headrest with slight extension.
- Perform proper surgical time-out.
- Prep and drape the patient.
- Placement of Dingman mouth prop or dental mouth prop.
- Place several retraction sutures on the lip to aid in retraction/visualization.
- Identify Stensen duct.
 - Artery and flap should be anterior to the duct.
- Use handheld Doppler to identify the course of the facial artery.
- An obliquely designed flap is centered over the artery from retromolar trigone area to gingival buccal sulcus at alar base (should be anterior to Stensen duct).
 - Flap is 1.5 to 2 cm wide.
- Incise mucosa at distal end (either superiorly or inferiorly based) through mucosa and buccinators.
- Identify facial artery and ligate.
- Elevate flap deep to the artery taking a small cuff of buccinator muscle and orbicularis muscle (**TECH FIG 4A**).
 - Flap can be 8 to 9 cm in length.
 - This flap can be elevated bilaterally if needed.
- Prepare fistula site so that some nasal mucosa can be rolled in (complete nasal mucosa closure is not critical) (**TECH FIG 4B**).

- Make certain to elevate raw edges of oral mucoperiosteal tissue to inset the flap.
- Rotate flap into defect and sew in place attaining excellent approximation of mucosal edges (**TECH FIG 4C**).
- Flap will need to be rotated posteriorly behind dental arch or through space in dental arch that can be protected from masticatory trauma (can use oral splints on teeth as well).
- Close donor site in two layers (buccinator muscle and then mucosa) taking care to avoid the Stensen duct.
- Place tongue stitch and remove Dingman/dental mouth prop.

TECH FIG 4 • A. Design of a facial artery

musculomucosal flap. **B.** Preparation of the fistula site.
C. Flap inset.

■ Tongue Flap (Anteriorly Based)^{9,11}

Raising and Insetting Flap

- Oral endotracheal tube placement to the right or left side; head placed in headrest with slight extension.
- Perform proper surgical time-out.
- Prep and drape the patient.
- Place bite block mouth prop.
- Inject palatal tissue with local anesthetic.
- Incise and elevate around palatal mucosa to become nasal floor.
 - Plan this incision so that you can have either complete nasal floor closure or at least significant nasal floor mucosa to place your tongue flap on.
- Close nasal floor if possible.
- Use the foil from a chromic stitch to make a template of the palatal defect.
- Place a traction suture through the tip of the tongue to improve exposure.
- Transpose the foil template onto the tongue with tip of flap at junction of anterior two-thirds and posterior one-third of the tongue.
- Mark out flap making certain to maintain at least a 2-cm pedicle base.
 - Can mark flap slightly larger than template for safety.
- Use a Colorado needle-tip Bovie to incise and elevate the flap from distal to proximal (**TECH FIG 5A**).
 - This dissection should include underlying longitudinal tongue musculature but can be thinned near the tip of the flap (down to 4 mm of muscle).
 - This dissection is not a natural tissue plane and can bleed from the raw muscle edge.
- Inset tongue flap into edges of raw mucoperiosteal palatal flaps (**TECH FIG 5B,C**).
- The use of 4-0 double-armed Monocryl sutures with the knots on the palatal mucosa makes inset of this flap much easier.
- This flap cannot be completely inset into the entire fistula as the pedicle width prevents complete inset (final inset is performed during division of

flap).

- Closure of donor site of the tongue with horizontal mattress sutures to prevent bleeding.
- Extubate patient.
- Place light elastics on orthodontic brackets for gentle MMF and patient comfort.
- Wait for 3 weeks for revascularization.

Division of Flap

- A gentle rubber shod clamp can be used to test if neovascularization has occurred in OR prior to division.
 - If concerns for insufficient vascularity, postpone division.
- Plan division so that a portion of the pedicled base will fill remaining portion of the palatal fistula.
 - For incomplete nasal floor closure, some secondary healing from margins can occur.
- Divide flap and debulk the new portion to inset (typically about 10%–15% of flap).
- Complete inset of flap.
 - Double-armed sutures make inset significantly easier.
- Return unused pedicled tissue to the tongue by opening previous incision and closing with chromic sutures.

TECH FIG 5 • **A.** Design of a tongue flap. Fistula before **(B)** and after repair **(C)** with a tongue flap.

■ Premaxillary Turnover Flap (Fish-Mouth Technique into Hard Palatal Mucoperiosteal

Flaps)¹²

- Midline oral endotracheal tube placement; head placed in headrest with slight extension.
- Perform proper surgical time-out.
- Place Dingman mouth prop.
- Prep and drape the patient.
- Mark junction of premaxillary gingiva and lingual side of incisors with lateral markings down the premaxilla along the cleft margin (**TECH FIG 6A,B**).
- Mark edge of mucoperiosteal flaps and lateral relaxing incisions along alveolar ridge (**TECH FIG 6C**).
- Inject with local anesthetic.
- Incise junction of the gingiva and lateral premaxilla and perform subperiosteal dissection of this flap.
 - The base of this flap narrows as you ascend toward the nasal cavity, so care must be taken in elevation (**TECH FIG 6D**).
- Use an angled blade to incise the edge of the mucoperiosteal flaps and make lateral relaxing incisions.
- Use a combination of periosteal elevators from lateral side and sharp scissor or knife dissection to re-elevate the mucoperiosteal flaps.

TECH FIG 6 • A,B. Design of the premaxillary turnover

flap. **C.** The mucoperiosteal flap is marked just behind the incisors and at the lateral borders of the premaxilla. **D.** Flap elevation. **E.** Flap inset in a parachute-type manner.

- Care must be taken to preserve greater palatine vessels if dissection occurs that distally.
- Advance mucoperiosteal flaps if possible.
- Turn over premaxillary flap for inset.
 - The premaxillary gingiva will become the new nasal mucosa, and the periosteum of the premaxilla will be the oral side for this flap.
- Use parachuting sutures to tack the periosteal side of flap to raw surface of mucoperiosteal flaps.
 - The use of double-armed sutures coming through the premaxillary flap and out the palatal mucoperiosteal flap makes inset and parachuting much easier (see **TECH FIG 6A**).
 - Do not attempt to tie these sutures until all have been placed for ease of placement.
 - Place sutures about 1 cm apart.
- After flap has been inset distally, close lateral aspect of flap to any raw areas of alveolus gingiva.
 - Work distally to proximally to close down posterior alveolar fistula.
 - Using a P2 needle and Castroviejo needle drivers facilitates this closure.
- May cover this flap with a thin piece of ADM if single layer closure is being performed.
- Place tongue stitch and remove Dingman device.

■ Free Tissue Transfer¹³

- Multiple donor sites have been described, including radial forearm free flap (**TECH FIG 7A**), anterolateral thigh free flap (**TECH FIG 7B**), and lateral arm flap.
- Thorough descriptions of and surgical techniques for the various free tissue flaps that have been described in the oncologic literature for palatal and maxillectomy defects are found in other chapters of this book.

TECH FIG 7 • A. Radial forearm free flap for palatal fistula closure. **B.** Anterolateral thigh flap for palatal fistula closure.

PEARLS AND PITFALLS

Obtain a preoperative retainer to protect repair for type IV and V fistulas

- Have this item made 2 weeks before surgery and have patient wear it to check for compliance and become habituated to it.
- Meet with your orthodontist and patient with retainer to make certain it fits but does not compress on your repair.

Postoperative compliance

- Must discuss and ensure proper postoperative compliance with diet and activities in the preoperative setting.
- This author has had recurrence secondary to poor postoperative compliance.

Preoperative orthodontia for tongue flaps

- Have orthodontic colleagues place temporary orthodontic brackets on the permanent teeth.
- Saves time of placing some form of appliance while under anesthesia.
- Use light elastics instead of true MMF to decrease intraoral opening while attempting to provide more comfort to the patient.

Preoperative evaluation for sleep-disordered breathing

- If planning posterior pharyngeal flap for type II or III fistula, evaluate for obstructive sleep apnea

	with preoperative polysomnogram.
Proper exposure and visualization	■ Make relaxing incision longer than expected. ■ Dissect around greater palatine vessels under direct visualization.
Mucoperiosteal flap rigidity	■ Remobilization of the mucoperiosteal flaps rarely provides as much mobility as desired as they are stiffer than primary repair.

POSTOPERATIVE CARE

- Patients should be observed overnight for pain control and to monitor for any airway issues.
- Patients should be started on a liquid diet for 24 to 48 hours after surgery (per surgeon's preference).
- Diet should then be advanced to a soft food diet for 3 to 4 weeks after surgery (per surgeon's preference).
- Some surgeons implement postoperative antibiotics, but the literature is divided about use.
- Peridex should be used (5 to 10 mL swish and spit) after every meal.
- Nasal precautions should be instituted.
 - No nasal suctioning while in hospital.
 - Avoid blowing of the nose.
 - Sneeze with an open mouth if possible.
 - No straws.
- If a postsurgical splint has been made, the retainer should be worn at all times and only taken out to clean.
- Follow-up within 1 week to assess healing.

OUTCOMES

- Recurrence rate is highly variable in the literature and dependent on technique/flap chosen and location of the fistula.¹⁴
- ADM shown to work in nine consecutive patients without recurrence for hard palatal fistula.⁶
- Buccal myomucosal flap has reported 7% to 18% failure rate for all uses.³
- FAMM flap has failure rates of 17% to 27%.¹⁰
 - Secondary to venous congestion and flap tip necrosis
- Lateral relaxing incisions and pushback technique have 10% failure rate.¹⁵

- All failures are reported in bilateral cleft lip and palate.
- Tongue flap reported failure rates range from 8% to 15%.^{9,16}
 - Sohail et al. found no difference in complications or recurrence rates between FAMM flaps and tongue flaps for closure of large anterior palatal fistula.
 - These authors found that the total operative time and fewer early postoperative complications with the FAMM flap.
- Free tissue transfer success rates are reported between 83% and 98%.¹³
 - Most studies did not address any donor site morbidity though.

COMPLICATIONS

- Acute postoperative airway obstruction
 - This situation can occur during emergence from anesthesia as tongue muscle tone can be slower to recover in patients compared with respiratory drive (effective glossoptosis).
 - Can also occur when a tongue flap has been used.
 - Prevention is key.
 - An oral airway device placed by the anesthesia team can disrupt/damage fistula repair.
 - Except in cases of tongue flap, I prefer to place a tongue stitch with 2-0 silk tied to a Raytec for resolution of acute postoperative glossoptosis.
- Bleeding
 - Raw surfaces are frequently left after fistula repair (particularly when relaxing incisions have been used).
 - Ensure hemostasis with normotensive anesthesia prior to extubation.
 - Tell family/patient to expect some oozing from the mouth or nose for 24 hours.
 - If nasal bleeding is severe, an endoscope can be used in the OR to evaluate the nasal repair.
- Recurrence¹⁴
 - The most common complication after palatal fistula repair
 - If a flap has been employed, usually from partial or full flap loss (see Outcomes section)
- Obstructive sleep apnea
 - Can occur if a PPF has been employed in Pittsburgh type II or III fistula repairs
 - May require modification, takedown of flap, or CPAP if persistent 6 months

after surgery

■ Halitosis

- Not a true complication but a frequent concern/question raised by family while wounds are healing

CHAPTER Velopharyngeal Insufficiency

Jennifer L. McGrath and Arun K. Gosain

DEFINITION

- Velopharyngeal insufficiency (VPI) refers to a structural inadequacy of the velopharyngeal apparatus, resulting in inadequate closure of the velopharyngeal port during speech.
- VPI may be congenital or acquired.
- It is characterized by nasal air emission and hypernasality of speech, articulation errors, decreased speech intelligibility, and nasal reflux of food and liquids.

ANATOMY

- The velopharyngeal sphincter is a complex, 3D arrangement of muscles that serves to separate the nasal cavity from the oral cavity during speech and swallowing.
- Muscles of the soft palate: levator veli palatini, tensor veli palatini, palatoglossus, palatopharyngeus, and musculus uvulae.
 - Paired levators are primarily responsible for velum closure by moving the velum posteriorly and superiorly.
 - Superior pharyngeal constrictor moves the posterior and lateral pharyngeal walls centrally.
- Innervation:
 - Predominantly CN IX and X: levator veli palatini and pharyngeal constrictors
 - CN V₃: Tensor veli palatini
- Three patterns of closure have been described:
 - Coronal: majority of closure from posterior movement of the velum
 - Sagittal: majority of closure from medial movement of the lateral pharyngeal

walls to meet the velum

- Circular: contributions of both movement of the velum posteriorly and movement of the lateral pharyngeal walls medially. Passavant ridge may contribute to closure.

PATHOGENESIS

- The cause of VPI may be structural, functional, or dynamic.
- Four main categories of VPI are frequently encountered. They include
- Palatoplasty: after primary cleft palate repair
 - Inappropriate levator veli palatini positioning
 - Palatal scarring preventing functional contraction of repaired levator sling
 - Length discrepancy preventing contact with the posterior pharynx
- Submucous cleft palate (SMCP)
 - May be classic (bifid uvula, palatal muscle diastasis) or occult
 - Often present later than cleft lip and palate
 - Not always associated with VPI (see section Natural History below)
- Palatopharyngeal disproportion
 - No anatomic abnormality to reconstruct
 - Disproportion may result from a short palate and/or a deep nasopharynx.
 - May be seen after tonsillectomy and adenoidectomy
- Neurogenic
 - More common in adults than children
 - Etiology may be upper motor neuron, nuclear, or lower motor neuron or generalized hypotonia.
 - Examples: muscular dystrophy, neurofibromatosis, cerebral palsy, apraxia, dysarthria
 - This subset tends to do more poorly with surgery.

NATURAL HISTORY

- Transient VPI is common after primary palatoplasty.
 - Patients are referred to speech-language pathologist (SLP) as early as 2 weeks postoperatively.
 - Perceptual speech assessment (PSA) by a SLP is obtained when the patient is of a cooperative age, often age 3 or above.
 - The incidence of lasting VPI after primary palatoplasty is about 10% to 20%.^{1,2}
- Submucous cleft palate (SMCP)

- Not all patients with SMCP will develop VPI. Studies suggest roughly 5% to 10% of patients with SMCP will develop VPI warranting intervention.^{3,4}
- The incidence of VPI in the pediatric plastic surgery population is higher due to referral bias.
- Children with SMCP should undergo PSA by a SLP. Intervention should be delayed until reliable PSA can be performed by a trained SLP, which is usually after age 3 years.
- Some children with SMCP may improve with speech therapy. Surgery is indicated for SMCP only when VPI is present and cannot be corrected with speech therapy.
- VPI caused by palatopharyngeal disproportion tends to worsen as the tonsils and adenoids regress or are surgically removed.
- In general, if VPI is diagnosed on PSA by an SLP and is secondary to previous palatoplasty, submucous cleft palate, or palatopharyngeal disproportion, VPI will persist indefinitely.
- Speech outcomes are better when surgery is performed at a younger age, but there is not a specific age cutoff for surgical treatment. However, misarticulations are harder to correct as a child ages.

PATIENT HISTORY AND FINDINGS

- Patients are frequently identified by parents, teachers, and/or SLPs.
- Patients with a history of cleft palate are frequently followed by SLP as part of a multidisciplinary approach to cleft care.
- Patients and parents may report nasal regurgitation, liquids worse than solids.
- Hypernasal speech and nasal air emission are the classic findings. Nasal air emission is normally only observed in /m/ and /n/ sounds.
- Compensatory articulations occur when patients are unable to seal off the nasopharynx.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- PSA by an SLP. Note that PSA is a *subjective* assessment of speech, one component of which is nasal air emission.
- Nasometry: *objective* test of nasal air emission, which can correlate subjective assessment of nasal air emission on PSA
- Imaging is indicated when VPI is documented on PSA.^{2,4}
- Multiview videofluoroscopy
 - Quantify lateral wall motion on AP view

- Quantify velopharyngeal gap on lateral view
- Requires reference landmarks for quantification
- Nasendoscopy
 - Qualitatively assesses closure pattern
 - Helpful in identifying stigmata of SMCP in patients without overt clefting
 - Roughly quantifies closure ratio: fraction of the diameter of the velopharyngeal port that is closed off during attempted sphincter closure
 - Nasendoscopy does not provide reference landmarks, so it cannot quantify motion and gap as in videofluoroscopy. It does allow visualization of nasopharyngeal and oropharyngeal structures, such as the adenoids.

DIFFERENTIAL DIAGNOSIS

- Although the vast majority of patients will present with a history of previous palatoplasty or submucous cleft palate, it is important to recognize other mechanisms of velopharyngeal dysfunction that are less adequately treated with surgery.
- Velopharyngeal mislearning
 - Articulation errors with no anatomic disturbance; treat with speech therapy
- Velopharyngeal incompetence: neurologic or neuromuscular origin
 - Globalized hypotonia with no structural abnormalities
 - Poor muscular competence of the lip and tongue may predict poor surgical outcomes. However, many patients will benefit from traditional surgical approaches.

NONOPERATIVE MANAGEMENT

- Speech therapy: all patients should be evaluated and treated by an SLP prior to intervention to minimize articulation errors.
- Prosthetics
 - Speech bulb
 - Palatal lift
 - Disadvantages: compliance, fit, growth
 - Prosthetics may be a helpful training tool in conjunction with surgery to improve oromuscular coordination and articulation placement.
- If a true mechanical insufficiency exists, nonoperative management is not recommended if a patient can tolerate surgery.

SURGICAL MANAGEMENT

- The overall goal of surgical management is to recapitulate a velopharyngeal port that can be closed during speech.
- Surgical approach typically depends on deficiencies seen on videofluoroscopy and/or nasendoscopy. Common approaches include
 - Intravelar veloplasty
 - In cases of SMCP only, primary palatoplasty with intravelar veloplasty repositions the aberrant insertion of the levator veli palatine muscles to create a functional sling.
 - This approach does not increase palatal length and is often passed over for Furlow palatoplasty.
 - Furlow palatoplasty or double-opposing Z-plasty (DOZ)
 - Initially described by Leonard Furlow as a technique for primary repair of cleft palate, this technique has gained favor as an approach to the management of VPI due to its ability to lengthen the palate via Z-plasty while also opposing the levator veli palatini muscles to recreate an anatomic muscular sling.
 - The major benefits of this technique are as follows:
 - It does not mechanically alter the closure mechanism of the velopharyngeal port, leaving open the option of other surgical techniques for refractory cases.
 - It is not associated with airway obstruction as are other techniques.
 - Dynamic sphincter pharyngoplasty
 - Dynamic sphincter pharyngoplasty (DSP) uses myomucosal flaps transposed to the posterior pharynx to create a smaller, circular velopharyngeal port.
 - This procedure is typically selected for patients with a coronal or circular closure pattern. When lateral wall movement is poor, DSP narrows the velopharyngeal port and adds bulk to the posterior pharyngeal point of velum contact.
 - The senior author has advocated use of the DSP in conjunction with the DOZ in cases of large velopharyngeal gaps.⁵
 - Pharyngeal flap pharyngoplasty
 - Based on the palatopharyngeal adhesion described by Passavant in the 1800s, pharyngeal flaps have been described as a surgical treatment for VPI for over a century.
 - Superiorly based pharyngeal flaps are widely utilized as a preferred

treatment for VPI.

- We describe a high inset pharyngeal flap, which is used as a last resort procedure due to its association with airway obstruction.
- Posterior pharyngeal wall augmentation
 - In cases of small gaps, implants and injectables have been used to augment the posterior wall of the pharynx to reduce the velopharyngeal gap.
 - Like many other applications of implants, implants in the posterior pharynx have been associated with failure due to migration, extrusion, and infection.
 - Silicone, Teflon, Gore-Tex, and polyethylene implants and calcium hydroxyapatite injections have been used. Despite successful reports, these techniques have not enjoyed widespread acceptance.
 - Autologous fat grafting has gained popularity recently but is in need of standardized protocols and prospective studies to evaluate retention of the augmentation and its utility over time. Still, it is most likely only useful in small velopharyngeal gaps.⁶⁻⁸

Preoperative Planning

- Surgical procedures are usually selected based on the preoperative closure pattern and velopharyngeal closure gap.⁹⁻¹¹
- For sagittal closure, velum may be too short and/or not move well, but lateral wall movement is preserved; therefore:
 - For small gaps less than 9 mm, we recommend double-opposing Z-plasty (DOZ) to lengthen the palate.
 - For gaps larger than 9 mm, we recommend a superiorly based pharyngeal flap.
- For coronal closure patterns in which lateral movement is poor, we recommend dynamic sphincter pharyngoplasty (DSP).
 - For gaps less than 9 mm, we recommend DSP alone.
 - For gaps greater than 9 mm, we recommend DSP in conjunction with DOZ.
- For circular closure patterns, many approaches have been used. DOZ may be used in smaller gaps. Narrow pharyngeal flaps or sphincter pharyngoplasty is recommended for larger gaps.²
- Pharyngeal flaps may have better outcomes in noncoronal closure patterns.⁹
- DSP may be most appropriate in coronal and circular closure patterns.¹⁰
- Combined DOZ and DSP can be used in very large velopharyngeal gaps.^{2,5,12}

- Nasendoscopy can identify the point of maximal constriction and evaluate adenoid tissues for flap inset planning.

Positioning

- The patient is placed in the supine position on the operating table.
- A shoulder roll can be used to gently extend the neck.
- The head of the operating table can be extended to aid in visualization.
- The face and neck are prepped and draped such that the infraorbital face and submandibular region are adequately exposed.
 - Intraoral prep with chlorhexidine or Betadine swabs
 - Eyelids are taped closed to prevent corneal abrasions.
- A nasal RAE tube should be used for intubation.
- A Dingman retractor exposes the posterior pharynx and retracts the tongue inferiorly.

TECHNIQUES

■ Furlow Palatoplasty or Double-Opposing Z-Plasty

Markings

- Z-plasty flaps are designed in two layers, oral and nasal, with one mucosal and one myomucosal flap in each layer.
 - Oral flaps: posteriorly based myomucosal flap and anteriorly based mucosa-only flap. By convention, the muscle-mucosa flap is on the patient's left side for the right-handed surgeon.
 - Nasal flaps: designed in opposite orientation to the oral flaps with a posteriorly based myomucosal flap (right side) and anteriorly based nasal mucosa flap
- The anterior limbs are designed near the junction of the hard and soft palate. Rather than the traditional 60-degree Z-plasty, we recommend a more obtuse angle, roughly 80 to 90 degrees.
 - Cheating the placement of the anterior limb to the more elastic soft palate tissue facilitates flap transposition (**TECH FIG 1**).

Dissection

- Oral flaps are incised and elevated. The surgeon should be conservative with the lateral extent of the mucosal incision as this dictates the inset location of the tip of the contralateral flap (**TECH FIG 2A,B**).
- It is critical to carefully identify the levator musculature within the myomucosal flaps to ensure recapitulation of the levator sling.
 - A muscle stimulator can aid in identification of functional muscle and facilitate complete release of muscle from scar in secondary palatoplasty. If a muscle stimulator is used, it is important to let the anesthesiologist know to avoid muscle relaxants or allow the relaxants to wear off prior to use of the muscle stimulator.
 - The muscle dissection often extends submucosally laterally to fully release the levator (**TECH FIG 2C**).
- Nasal flaps are transposed in the standard Z-plasty fashion, with the posteriorly based left-sided myomucosal flap rotated right and posterior and the mucosal flap left and anterior (**TECH FIG 2D**). The limbs of the nasal mucosa are closed with simple interrupted dissolvable sutures.
- Oral flaps are transposed in a similar manner. Transposition of the oral myomucosal flap completes reconstruction of a competent levator sling. The oral mucosal limbs are then closed (**TECH FIG 2E**).

TECH FIG 1 • Markings for double-opposing Z-plasty. Z-plasty marked on the oral mucosa. The posteriorly based oromuscular flap is marked on the patient's left

side for a right-handed surgeon (the end of the oromuscular incision is designated by the pointer). Note the curved arm of the anteriorly based Z-plasty (*arrow*) as well as its obtuse angle to the midline incision.

TECH FIG 2 • Double-opposing Z-plasty. A.

Posteriorly based oromuscular flap, held in forceps, is being elevated. **B.** Marking of anteriorly based nasal mucosa Z-plasty (*black arrow*) after dissection of the posteriorly based oromuscular flap, retracted posteriorly and laterally with forceps. Incisions have been made to elevate the anteriorly based oral mucosal Z-plasty (*white arrow*). **C.** Using a sweeping motion from anterior to posterior, the posteriorly based nasomuscular flap (*arrow*) is elevated and transposed posteriorly and toward inset on the patient's left side. **D.** Transposing the nasomuscular flap. Right-sided nasomuscular flap (forceps) is rotated posteriorly and to the left, bringing the levator muscle into anatomic position. **E.** Final closure of the double-opposing Z-plasty.

■ Dynamic Sphincter Pharyngoplasty

Markings

- The uvula can be reflected into the nasopharynx by suturing the tip to a red rubber catheter passed through the naris.
- The level of inset is based on the position of the adenoids (**TECH FIG 3A**).
 - Adenoids that extend inferiorly may hinder the ability to inset the flaps as adenoid tissue does not hold sutures well. Low-lying adenoid tissue should be identified preoperatively on nasendoscopy.

- If the caudal extent of the adenoids is thought to compromise cephalic inset of the sphincter pharyngoplasty, then an inferior adenoidectomy should be considered prior to sphincter pharyngoplasty. In this case, we recommend delaying sphincter pharyngoplasty for at least 3 months following adenoidectomy.
- Superiorly based myomucosal palatopharyngeus flaps are designed on the posterior tonsillar pillars.
 - The base of the flaps should be designed at the level of inset (**TECH FIG 3B**).
 - A high inset should be anticipated, as the inset should be designed at the anticipated level of velopharyngeal contact during phonation.

Dissection

- Palatopharyngeus flaps are elevated to the height of the desired new nasopharyngeal port, typically the level of velum opposition from preoperative videofluoroscopy (**TECH FIG 4A**).
- Flaps are transposed to the posterior pharyngeal wall and inset in a transverse arrangement directly posterior to the desired nasopharyngeal port location. Flaps may be inset in a stacked or end-to-end manner (**TECH FIG 4B**).
- The size of the new sphincter should be roughly one fingerbreadth.
- Donor sites in the posterior tonsillar pillars are closed primarily with dissolvable sutures (**TECH FIG 4C**).

TECH FIG 3 • A. Horizontal marking at the level of inset of the sphincter pharyngoplasty. The position of the adenoids (*arrow*) may limit the superior extent of

inset of the sphincter. **B.** Incision along the left posterior tonsillar pillar (*arrow*). Myomucosal flaps based on the palatopharyngeus are marked bilaterally.

TECH FIG 4 • A. Elevating the left posterior tonsillar pillar, held in forceps, to the level of desired inset at the base of the adenoids. **B.** Setting the tension of the bilateral myomucosal flaps (tonsillar pillars). Flaps can be inset end to end or overlapping, depending on the desired tension. In this illustration, the tonsillar pillars are held in forceps in an overlapping configuration. **C.** Final inset of dynamic sphincter pharyngoplasty. Myomucosal flaps are inset (*arrow*) and donor sites are closed primarily (not shown).

■ Posterior Pharyngeal Flap

Markings

- Superiorly based myomucosal flap is marked on the central posterior pharyngeal wall. The base of the flap must be designed with awareness of the three-dimensional relationship of the flap to the velum. The width of the flap may vary depending on the velopharyngeal gap (**TECH FIG 5**).
- A transverse incision for flap inset is designed on the nasal side mucosa anterior to the uvula.
- A counterincision on the oral side creates a tunnel to pass and secure the flap. This transverse incision is located near the hard-soft palate junction. Incisions must be wide enough to accommodate flap width.

Dissection

- The pharyngeal flap is elevated deep to the pharyngobasilar fascia and superficial to the prevertebral fascia (**TECH FIG 6A**). This is crucial to safe use of this technique in cases of velocardiofacial syndrome (VCFS) in which the carotid arteries can be medially displaced.
 - The carotid vessels lie deep to the prevertebral fascia and therefore will not be damaged irrespective of possible medial transposition, as long as the dissection remains superficial to the prevertebral fascia.
- A tunnel is created through the nasal and oral palate transverse incisions. This then allows the pharyngeal flap to be passed through using a clamp or forceps (**TECH FIG 6B–E**).
- Flap is inset into the oral mucosal incision. The tip of the flap is anchored to the periosteum at the posterior aspect of the hard palate to provide resistance to constriction and descent during healing.
- The donor site is closed with dissolvable sutures if possible. If too large to close primarily, it can be left raw to mucosalize. The posterior soft palate incision is also left to heal secondarily (**TECH FIG 6F**).
- Port size is checked by manual palpation using a finger. The new ports are typically stented in some manner. We choose 3-Fr endotracheal tubes trimmed short and passed through the nares into the ports.

TECH FIG 5 • Marking of the superiorly based posterior pharyngeal flap. The location of the base of the flap can be determined by preoperative imaging.

TECH FIG 6 • A. Flap elevation. The pharyngeal flap is elevated in a plane immediately superficial to the pharyngobasilar fascia. **B–E.** Flap inset into the velum. Incisions are made on the nasal (**B**) and oral (**C**) mucosa of the posterior soft palate to allow flap inset. A tunnel (**D**) is created between these incisions, and the flap is passed through and inset into the oral incision (**E**). **F.** Final appearance after pharyngeal flap inset. The posterior pharynx donor site is closed primarily.

Tongue edema	■ Release of the Dingman retractor every 90 minutes for 2 minutes reduces tongue edema and eliminates the need for a tongue stitch postoperatively.
Velocardiofacial syndrome (VCFS)	■ VCFS disrupts the algorithm because outcomes are usually poorer. ■ Assessment is the same, and selection of operation is not necessarily different. However, care must be taken during dissection to ensure surgical plane is deep to the pharyngobasilar fascia and superficial to the prevertebral fascia

DOUBLE-OPPOSING Z-PLASTY

Flap design	■ Design mucosal flaps more obtusely (80–90 degree) and arch to the desired end point. ■ The oral myomucosal flap back cut should be posterior enough from the hard palate junction to lie within elastic soft palate tissue to facilitate closure. Placing the back cut too close to the hard palate will make it more difficult to achieve closure of the oral mucosa ■ Limit the back cut of the anterior limbs of the mucosal flaps again to reduce difficulty closing. Muscular incision and dissection can extend beyond the mucosal incision.
Flap handling	■ Careful flap handling, particularly of flap corners, is key to a satisfactory result.

DYNAMIC SPHINCTER PHARYNGOPLASTY

Low adenoids	■ Adenoid position should be assessed preoperatively. ■ Attempts to inset the flaps into the adenoids will be unsuccessful and the adenoid tissue does not structurally hold sutures well. ■ If adenoids are particularly inferior, consider preoperative inferior adenoidectomy. ■ Inferior adenoidectomy should be at least 3 months prior to pharyngoplasty.
Flap inset	■ Inset the flaps as high as possible, often immediately below the adenoids (2 mm inferior). ■ Flaps should be inset at the point of maximum constriction, Passavant ridge, if developed.
Flap tension on inset	■ Flaps can be inset overlapping or tip to tip. ■ They should be placed on slight resting tension with residual elastic tone. ■ Too tight at inset can cause airway obstruction.

- Too loose at inset can cause persistent VPI.

PHARYNGEAL FLAP PHARYNGOPLASTY

Flap design	■ Width of the flap should be tailored to the patient's needs.
Flap lining	■ Line as much of the pharyngeal flap as possible. The raw surfaces will contract and the flap will narrow, creating a larger distance for the lateral pharyngeal walls to move for closure.
Flap descent	■ Flaps tend to narrow and pull inferiorly over time. ■ High inset allows more lining of the raw surface as well as a better anchor to the hard palate, resisting contraction and descent. ■ High inset also shortens the exposed raw surface.

POSTOPERATIVE CARE

- Patients are observed in the hospital overnight for signs of airway obstruction.
 - Some surgeons place a tongue stitch at the conclusion of the procedure to assist in clearing tongue-base obstruction in the postoperative period.
 - Similarly, IV dexamethasone can be useful to reduce airway and tongue edema in immediate postoperative period.
- Although preoperative antibiotics are frequently given, postoperative prophylactic antibiotics are not routinely used, as there is no evidence to support their efficacy.
- Stenting of the reconstructed ports:
 - Pharyngeal flap: Nasopharyngeal stents are left in place for 1 week postoperatively to prevent synechiae, while the raw surfaces of the pharyngeal flap are remucosalizing to maintain the newly constructed nasopharyngeal ports. We opt to use two small endotracheal tubes cut short that are passed through each naris into the pharynx. These are sutured to the caudal septum for stability. Tube size depends on the size of the ports, but a size 3 is often adequate.
 - DSP: A larger caliber truncated endotracheal tube may be passed from the naris into the new port, but this is usually not necessary unless the reconstructed port is very tight. DSP is less prone to synechiae as there are fewer raw surfaces at the completion of the reconstruction.
- Oral rinses, especially after feeding, can help maintain oral hygiene. Older children may be prescribed chlorhexidine rinses if they are likely to be compliant with swishing and spitting. Alternatively, plain water rinses can aid

in clearance of food and liquids from the oropharynx and flaps. We recommend that all patients drink clear liquids after eating to assist in clearance of food debris.

- Patients are placed on a soft diet for 6 weeks postoperatively. They are also instructed to drink from a cup only—no straws or suction.
- Patients return for follow-up 1 to 2 weeks postoperatively for an early incision check and at 6 weeks for a final assessment. At 6 weeks, all restrictions are lifted. If a fistula were to develop, this would most likely be visible at the 6-week appointment.
- Nasal resonance and articulation speech therapy are resumed after 6 weeks.
- PSAs are delayed until a minimum of 3 months postoperatively to allow for complete resolution of edema.

OUTCOMES

- Correction of VPI occurs in 80% or more of surgical patients, with slight variation across techniques. Head-to-head comparisons of techniques are difficult because most studies are based on treatment algorithms with groups differing in both preoperative VPI characteristics and surgical approach.
- Randomized trials of DSP and pharyngeal flaps have shown no difference in residual VPI.^{1,13}
- DSP: 80% to 85% of patients demonstrated resolution of hypernasality.¹⁴
- Pharyngeal flap: 85% to 95% improvement or resolution of VPI^{1,11,15}
- DOZ: 75% to 85% improvement or resolution of VPI^{11,16,17}
 - DOZ may be slightly less effective in resolving VPI, but this is dependent on velopharyngeal gap size, supporting the use of an algorithmic approach to procedure selection.¹⁸

COMPLICATIONS

- Bleeding
 - Velocardiofacial syndrome: It is important to identify medial displacement of the carotids as this may alter surgical plan. Preoperative imaging with CTA or MRA is often obtained.
- Airway obstruction
 - Obstruction may occur acutely postoperatively or chronically.
 - Acutely, related to airway or tongue edema
 - Chronically, related to inadequate size of pharyngeal port

- Pharyngeal flap has the highest incidence of obstruction.
 - Incidence of acute airway obstruction is as high as 38%,¹⁹ but most resolve within the first few months postoperatively.
 - Chronic obstruction/obstructive sleep apnea incidence is roughly 10%. Pierre Robin sequence patients may be more susceptible.^{20,21}
- Sleep studies are useful in evaluating and quantifying obstruction.
- Obstruction can be treated with CPAP or flap takedown in severe cases.
- Dehiscence or fistula: may be assessed at the 6-week visit, but we recommend waiting at least 6 months to intervene surgically.
- Scarring: particularly in the DOZ, scarring can limit functionality of the repair. We again emphasize dissection of functional muscle free from scar. Use of intraoperative muscle stimulation can serve as a guide to the distinction of functional muscle from scar.

Section III: Cleft Rhinoplasty

15

CHAPTER Secondary Cleft Rhinoplasty

Ali Totonchi and Ji H. Son

DEFINITION

- Rhinoplasty remains one of the most challenging plastic surgery procedures for cleft patients. These patients present years after the initial cleft repair to correct residual nasal deformities.
- The nature of the procedure varies from patient to patient depending on the nasal deformities. Systematic reorientation of distorted nasal architecture and creation of a balanced platform for the lower lateral cartilages constitute some of the cardinal principles for correcting the cleft lip nose deformities.

ANATOMY

- Radix is the depth of the nasal root at the nasofrontal angle. This angle connects the brow and the dorsum through a soft concave curve. Although this angle can vary from 128 to 140 degrees, it is ideally 134 degrees in females and 130 degrees in males.
- Nasal dorsum is assessed using the curvilinear dorsal aesthetic lines traced from the supraorbital ridge to the tip-defining points. Ideally, the width of the dorsal aesthetic lines should match the width of either the tip-defining points or the interphiltral distance.
- Nasal deviation is evaluated by drawing a line from the mid-glabellar area to the menton, bisecting the nasal ridge, upper lip, and Cupid bow. Deviation of the nose from this line would most likely require septal surgery for correction.
- The upper lateral cartilage (ULC) overlaps the nasal bones, septum, and the lower lateral cartilages (LLCs). The internal valve is the angle formed by

intersection of the nasal septum and the caudal margin of the ULC.

- LLCs comprise medial, middle, and lateral crura, which are connected to each other, the ULCs, and the septum by fibrous tissue and ligaments. Modification in any of these structures alters tip projection.
- The nasolabial angle is used to determine the degree of tip rotation. This angle is obtained by measuring the angle between a line coursing through the most anterior and posterior edges of the nostril and a line dropped perpendicular to the natural horizontal facial plane. This angle should be between 103 to 105 degrees in women and 95 to 100 degrees in men.
- The septum, turbinates, and nasal valves (internal and external) serve as the anatomic functional foundation for the nose, by contributing to respiration, filtration, humidification, temperature regulation, and protection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Although nasal deformities are partially corrected during cleft lip surgery, patients often present years after the initial cleft repair to correct residual nasal deformities.
- Efforts to correct nasal deformity in patients between the ages of 4 and 14 years may have a significant chance of supratip deformity and loss of tip definition, with widening and thickening of the skin.
- Many patients with bilateral and complete cleft lip deformities have other craniofacial abnormalities, particularly deformities of the maxilla. Correction of the skeletal deformity sets the stage for a more successful correction of the nasal deformity.
- Approximately 60% of patients with cleft lip nasal deformity have difficulty breathing through the nose. Correction of physiologic function of the nose should be addressed at the time of correction of the nasal deformity.
- Many of the patients may have asymmetry involving parts other than the nose and the lip. Therefore, it is important to assess the entire face and note asymmetry before analyzing the nose in detail (Table 1).¹

Table 1 Detailed Nasal Analysis

Structure	Assessment
Skin	• Thickness • Quality of the tissue for reconstruction
Nasal bone	• Symmetry

	• Length • Distance from the midline • Depth of radix • Presence or absence of a dorsal hump
Midvault	• Upper lateral cartilage collapse • Vertical symmetry
Nasal tip	• Shape—bulbous, boxy, narrow, or parenthesis deformity? • Symmetry • Fullness • Projection • Infratip lobule size • Nasolabial angle • Direction of the columella
Alar base	• Comparison of thickness of the ala • Vertical position • Configuration of nasal sill
Nostrils	• Symmetry
Internal nose	• Stenosis of the internal and external valve • Presence or absence of a deviated septum • Size and shape of the turbinates • Synechiae • Septal perforation

Table 2 Features of Unilateral Cleft Lip Nasal Deformity

- The columella is shorter on the cleft side.
- The base of the columella is deviated to the noncleft side.
- The lateral crus of the lower lateral cartilage is longer on the cleft side.
- The nasal tip is displaced in both the frontal and the horizontal planes.
- The nasal tip is asymmetric.
- The ala is flattened, resulting in horizontal orientation of the nostril.
- The nostrils are asymmetric.
- The entire nostril is repositioned because of the deficiency in the underlying frame.
- The base of the ala is displaced laterally and/or posteriorly and sometimes inferiorly.
- The nasal floor is caudal on the cleft side.

- A nasolabial fistula could be present.
- The septum and anterior nasal spine are shifted toward the noncleft vestibule.
- The nasal septum is deviated, resulting in a varying degree of nasal obstruction.
- The inferior turbinate on the cleft side is hypertrophic.
- The maxilla is hypoplastic on the cleft side.
- The premaxilla and the maxillary segments are displaced.

From Guyuron B. MOC-PS(SME) CME article: late cleft lip nasal deformity. *Plast Reconstr Surg.*

2008;121(4):1-11, with permission.

- It is crucial to recognize common features of unilateral cleft lip nasal deformity (Table 2) and bilateral cleft lip nasal deformity (Table 3).¹

Table 3 Features of Bilateral Cleft Lip Nasal Deformity

- The columella is relatively short and the prolabium seems attached to the nasal tip.
- The nasal tip is flat and broad.
- The nasal alae are flat and sometimes drawn in an S-shaped fashion.
- The base of the ala is displaced laterally and sometimes inferiorly on both sides.
- Both nostrils are oriented horizontally.
- The lower lateral cartilages are severely deformed.
- The nasal floor is absent.
- The caudal cartilaginous septum and the nasal spine are displaced inferiorly relative to the level of the alar bases.
- The nasal tip and the nostril are commonly asymmetric.

From Guyuron B. MOC-PS(SME) CME article: late cleft lip nasal deformity. *Plast Reconstr Surg.*

2008;121(4):1-11, with permission.

IMAGING

- Imaging is not indicated for all of the patients undergoing secondary cleft rhinoplasty unless there is airway obstruction from sinus or cephalic septal pathology necessitating further imaging to aid in surgical planning.

SURGICAL MANAGEMENT

- One of the most important aspects of cleft lip rhinoplasty is the creation of symmetric nose.

- Patients commonly have maxillary deficiency and may need orthognathic surgery and maxillary bone grafting. Ideally, if maxillary surgery is contemplated, it should precede repair of the cleft lip rhinoplasty deformity.
- Maxillary advancement is not advised before the age of 14 to 15 years for a female patient and 17 to 18 years for a male patient, unless serial cephalograms or hand radiographs demonstrate completion of bone growth before this age.
- Otherwise, the patient may need another maxillary advancement if the maxilla is advanced and the mandible continues growing, which can alter the outcome of the initial cleft lip rhinoplasty.
- The operation may be performed through an endonasal or an open technique. Because of common asymmetry in the nasal frame, cleft lip–related nasal deformities are usually more successfully corrected through an open technique.
- The advantages of an open technique are excellent exposure, good hemostasis, and flexibility in corrective procedures.
- The main objectives of the operation are to restore symmetry and harmony to the face as well as improve functional outcome.
- The nature of the operation varies tremendously from patient to patient.

Preoperative Planning

- Discuss risks, benefits, and expectations with parents and patients on the day of surgery. Specifically outline the risks including asymmetry, incomplete resolution or suboptimal correction of nasal deformities, and additional operations.
- It is paramount to do a detailed facial and midface analysis to address each component of the nasal deformity before the operation.

Positioning and Approach

- The patient is positioned supine.
- Depending on the choice of cartilage graft, either the ear or the chest wall is prepped in addition to the face.
- Previous incisions are used to minimize creating new scars when possible.

TECHNIQUES

■ Open Cleft Lip Rhinoplasty

Incision and Dissection

- Incise the columella at the mid-columella, a stair-step incision helps to realign the columella at the end of the procedure (**TECH FIG 1A**). When possible, use an old scar in the nasal vestibule and avoid making a new incision.
 - Extend the incision behind the columella and upward, continue as an infracartilaginous incision on the noncleft side.
 - On the cleft side, the incision is made to match the noncleft side, which may not coincide with an infracartilaginous incision.
- Dissect the columella. Find the loose areolar space between the medial crura and follow this upward in the lower lateral cartilage (LLC) to separate the LLCs from the fibrofatty tissue.
 - The dissection extends to the pyriform rim laterally and nasal bone superiorly and should be symmetrical on both sides to allow for symmetric contracture after the operation (**TECH FIG 1B**).
- The course of the operation varies from patient to patient depending on the nasal deformities.
 - In our example, we present a patient with short medial crus, low dome, and excessive soft triangle soft tissue (**TECH FIG 1C**).

Shape Correction^{1,2}

- After complete dissection and repositioning of the lower lateral cartilage on the cleft side, double hooks are placed to lift the alar domes symmetrically.
- A 30-gauge needle is used to facilitate alignment of the medial crura when the columellar strut is placed (**TECH FIG 2A**).

TECH FIG 1 • **A.** A columellar incision. **B.** In an open technique, the malformed lower lateral cartilage is exposed. The cleft lower lateral cartilage (*arrow*) has less projection relative to the noncleft side. **C.** Comparing the cleft side (*patient's left*) to the noncleft side (*patient's right*) with the skin retracted, the medial crus (*black arrow*) is shorter and the nasal dome (*white arrow*) is lower. From Guyuron B. MOC-PS(SME) CME article: late cleft lip nasal deformity. *Plast Reconstr Surg.* 2008;121(4):1-11, with permission.

TECH FIG 2 • **A.** Medial crus is tattooed to facilitate alignment when columellar strut is placed. **B.** Columellar strut is placed. **C.** Columellar strut is

secured using sutures. There is excessive soft triangle lining that will be trimmed (*arrow*). **D.** A shield graft is placed. **E.** Alar graft is placed for better shape and support. **F.** Internal and external splints are placed. From Guyuron B. MOC-PS(SME) CME article: late cleft lip nasal deformity. *Plast Reconstr Surg.* 2008;121(4):1-11, with permission.

- Tattoo marks can be made with methylene blue on either medial crus to mark the alignment.
- The columellar strut is fixed in position and 6-0 clear nylon sutures are placed in at least two or three sites guided by the previous tattoo marks (**TECH FIG 2B**).
- The final suture close to the domes will better align the medial crura. There is still excessive soft triangle lining that will be trimmed (**TECH FIG 2C**).
- A shield graft is placed in position to facilitate additional support and maintain central alignment of the nasal tripod (**TECH FIG 2D**).
- An alar rim graft is placed to support the ala in a better position, which will be further supported using external and internal stents (**TECH FIG 2E**).
- Upon completion of surgery, there is restoration of proper height and shape to the nostrils and the nasal tip; an external nasal silicone stent is positioned on the ipsilateral side to the cleft lip on the soft triangle (**TECH FIG 2F**).
- The columellar incision is closed using 6-0 fast-absorbing catgut.
- Turbinates are reduced to improve nasal airway passage, if needed.

■ Dorsal Correction

- Many patients require removal of a dorsal hump and reduction of the radix. Less frequently, there are patients with nasal deformities who may require augmentation of the radix and dorsum.
- Nasal bone deviation is corrected by nasal osteotomies when surgery is performed on skeletally mature patients. These techniques are discussed in the chapter on secondary rhinoplasty.
- If augmenting the radix and dorsum, diced cartilage graft can be utilized.
- Nasal bone asymmetry may require wedge osteotomy between the nasal

bone and the midline structures for medial repositioning of the nasal wall.

■ Nasal Framework Correction

- The upper lateral cartilage (ULC) usually needs correction through separation, trimming, and repositioning.
 - Most cleft lip noses benefit from spreader grafts.
- If required due to septal deviation, septoplasty should include resection of the posterior portion of the quadrangle cartilage, vomer bone, and perpendicular plate of the ethmoid bone, leaving a strong and straight L-shaped frame to support the nose.
 - This frame is straightened with or without scoring by application of bilateral spreader grafts anteriorly.
 - The septum is then splinted using either a pair of Doyle stents or custom-fabricated stents.
 - These stents are sutured in position using transseptal nonabsorbable sutures.
- The ULC is then fixed to the spreader grafts and the septum using 5-0 PDS suture (Ethicon Inc., Somerville, NJ).

■ Reshaping the Tip and Ala

- The dome on the affected side is posterior; the lateral crus extends laterally; and almost always, the medial crus is shorter than ideal, causing length deficiency in the columella.
 - A columellar strut is the most efficacious means of supporting the tip. Use of a columellar strut will:
 - Increase tip projection
 - Elongate the columella on the cleft side
 - Augment the subnasale, which is often deficient
 - Increase the nasolabial angle
 - Prevent the tip from shifting caudally
- Free up the lower lateral cartilage on the cleft side completely or bilaterally or advance in V-to-Y fashion to restore adequate projection on the cleft side.
- Reduce the thickness of the ala by removing some of the fibrofatty tissue, especially at the alar base and along the alar rim.

- Interdomal, transdomal, and lateral crural sutures may be required.
- A tip graft will only be used if the infratip lobule volume is inadequate, which is seldom the case.
- Placement of an alar rim graft and application of two stents externally and internally that are fixed with a through-and-through suture reduces the potential for recurrent alar thickening.

■ Nostril Correction

- Augmentation of the floor of the nostril and elevation of the nostril sill on the cleft side is achieved by placement of a cartilage graft.
- The alar bases are then narrowed as needed and repaired using 6-0 fast-absorbing catgut.

PEARLS AND PITFALLS

Physical findings

- Careful selection of patients at a suitable age is required along with a cooperative patient and a caregiver.
- Skeletal correction of the bony base must be performed before soft tissue correction.

Technique

- Use old scars and avoid new scars if possible.
- If length of the surgery lasts more than 1.5 hours, consider reinjecting vasoconstrictive agents to minimize bleeding intraoperatively and postoperatively.
- Restoration of the distorted structures should be based on normal anatomy.
- Careful tissue handling with meticulous alignment of landmarks is required.
- Forcing the cartilage anteriorly to achieve symmetry is doomed to failure, as the cartilage will gradually shift the tip to the cleft side of the nose.

POSTOPERATIVE CARE

- A nasal splint is applied for 7 to 8 days.
- Patients are asked to refrain from heavy exercise for 2 to 3 weeks and use of

eyeglasses for 4 to 5 weeks.

OUTCOMES

- Cleft lip rhinoplasty addresses both functional and aesthetic nasal disturbance following initial cleft lip repair.
- Patients are usually very satisfied following cleft lip rhinoplasty due to the resultant functional and aesthetic improvement.

COMPLICATIONS

- The most common complication of secondary cleft lip rhinoplasty is asymmetry. Patients should be informed that they might need additional surgery. Most common sites of asymmetry are the alar base and nostril.¹⁻³
- Owing to the underlying condition, these patients have a higher chance of nasal obstruction preoperatively and sometimes postoperatively.³
- Septal deviation may recur, or there may be residual septal deviation due to primary deformity. This may require additional procedures.

Section IV: Atypical Clefts- Soft Tissue Component

16 Tessier 3 and 4 Clefts (Nasal-Cheek Region)

CHAPTER

Philip Kuo-Ting Chen and Vikram S. Pandit

DEFINITION

- The Tessier no. 3 facial cleft occurs at the junction of the frontonasal and maxillary process.
 - It involves the position of an ordinary cleft lip extending upward and passing through the alar base towards the medial canthal region.
 - The medial part of the eye is displaced laterally and inferiorly (**FIG 1A**).
- The Tessier no. 4 facial cleft is located lateral to the no. 3 facial cleft.
 - This cleft starts lateral to the philtral ridge and travels lateral to the alar base toward the medial canthal region.
 - The medial part of the eye is displaced laterally and inferiorly (**FIG 1B**).

ANATOMY

- The Tessier no. 3 and no. 4 facial clefts have similar soft tissue abnormalities resulting in shortened oculo-alar and oculo-oral distances.
- In the lip region, the cleft line is the same as ordinary cleft lip in no. 3 (**FIG 2A**) and is lateral to the philtral column in no. 4 (**FIG 2B**).
- Both clefts are accompanied by distortion or disruption of the orbicularis oris muscle. The cleft extends upward into the cheek with alar involvement in no. 3 and without alar involvement in no. 4.
- In both clefts, orbital dystopia is coupled with globe abnormalities and underlying skeletal deficiencies.

- The medial canthus is displaced inferiorly, and the lacrimal canaliculus on the lower eyelid is usually disrupted.
- Usually, it is possible to identify the punctum of the lower eyelid (**FIG 3**).
- There is a coloboma of the lower eyelid (**FIG 4**).
- The involved muscles of facial expression are distorted in their orientation.
 - The alar base and the lateral part of the nasalis muscle are displaced upward, and the medial part of the cheek muscles is displaced downward.
- The underlying maxillary bone is depressed or separated according to the severity of the cleft.
- Patients may have independent pathology in their cheek region and lip (eg, an intact lip with the cleft only seen in the cheek region¹⁻⁴) (**FIG 5**).

HISTORY AND PHYSICAL FINDINGS

- The history taking and physical examination are similar to other patients with craniofacial anomalies.
- The history should include the family history, medications during the first trimester, and prenatal diagnosis.
- Physical examination should include the extent and location of soft tissue cleft, eye condition, involvement of alveolus, palate, and also other associated systemic problems.⁵

FIG 1 • **A.** Tessier no. 3 facial cleft. **B.** Tessier no. 4 facial cleft.

FIG 2 • **A.** The cleft lip of a Tessier no. 3 is similar to an ordinary cleft lip. **B.** The cleft lip of a Tessier no. 4 is lateral to the philtral column.

IMAGING

- Radiographic images are usually not necessary in the first visit.
- CT scanning is helpful to determine the extent of bony defect on orbital floor if the patient has severe orbital dystopia (**FIG 6**).

FIG 3 • The punctum can be identified lateral to the cleft.

FIG 4 • Coloboma of left lower eyelid.

- Panoramic x-rays and CT scans are also helpful to evaluate the necessity of bone grafting in the alveolar or cheek region when the patient is older (**FIG 7**).
- In the author's center, cephalometric and panoramic radiographs and CT scans with 3D reconstruction are routinely recorded every 2 years from ages 5 to 17 years to monitor facial growth.

SURGICAL MANAGEMENT

- Surgical correction of the soft tissue problems is undertaken between 3 to 6 months of age. This correction should aim at the restoration of normal facial appearance and protection of the eye.
- Bony reconstruction of the alveolar clefts is similar to the timing of alveolar bone grafting in cleft patients, ie, in the mixed dentition period before the eruption of the teeth in the cleft region.
- The bony reconstruction for the skeletal defects on the face and orbit is generally not undertaken till the patient is at least 3 years of age and more commonly at the age of 5 years.
- This allows the inner and outer tables of the calvarium to be split and therefore obtain a large amount of bone graft with minimal donor morbidity.
- However, when there is severe bony deficiency on the orbital floor causing a significant dystopia of the globe, orbital floor reconstruction should be considered at an earlier age.

FIG 5 • Tessier no. 3 cleft with cleft on cheek region and

intact lip.

FIG 6 • 3D CT scan of a right Tessier no. 4 facial cleft.

- The repair of the soft tissue deficit in the Tessier no. 3 and no. 4 craniofacial clefts is based on five basic components as outlined.⁶
- A medial canthopexy with 2 mm overcorrection in an upward vertical position
 - The postoperative scar contracture will always pull the new medial canthus inferiorly.
- Midface rotation advancement is performed with rotation of the medially based nasal flap, advancement of the laterally based cheek flap, and repositioning of the facial muscles.
 - This helps to lengthen the shortened oculo-oral and oculo-alar distances while restoring normal facial expression.
 - This is similar to the rotation-advancement repair in ordinary cleft lip.
 - The lengthening achieved in the midface region should primarily be due to muscle repositioning rather than skin Z-plasties.
- Placement of the surgical scars should be along the junction of the facial units, rather than placing multiple Z-plasties on the cheek, to avoid color

mismatching due to skin differences in the nasal and cheek regions.

- Placement of the scar lateral to the junction of the facial units will result in visible scars on the cheek region.⁷⁻¹¹
- Repair the cleft lip using the standard technique (ie, discard the redundant tissue lateral to the proposed philtrum to avoid an unnatural-looking lip).^{12,13}
- Downward and medially repositioning the involved alar base with 1 to 2 mm of overcorrection in vertical dimension
 - The postoperative scar contracture in cheek will always pull the alar base upward.

Positioning

- The soft tissue repair is performed under general anesthesia.
- The endotracheal tube is usually fixed to the center of the lower lip with tape.
- The patient is placed in supine position with the face disinfected and draped.

FIG 7 • Panoramic radiograph of a bilateral Tessier no. 4 facial cleft.

■ Markings

- With the patient prepared under general anesthesia, the key elements of the cleft lip are marked, excluding the skin lateral to the philtral column on the cleft side.
- On unilateral facial clefts, the markings for the anatomical landmarks are relatively easy.
 - The positions of the displaced medial canthus, the alar base, and the peak of the Cupid's bow can be determined by comparison with equivalent landmarks on the noncleft side (**TECH FIG 1A**).
 - It should be emphasized that the position of the medial canthus and the alar base should be overcorrected, ie, 2 mm higher for medial canthus and 2 mm lower for alar base (**TECH FIG 1B,C**).
- It is much more difficult to determine these landmarks in the presence of bilateral facial clefts.
 - However, the position of the medial canthus can still be determined by the position of the lateral canthus, together with the width of the eyes.
 - The position of the alar base is determined by the position of the columella and the vertical height of the lateral lip, which is further determined by the vertical height of the prolabial segment.

TECH FIG 1 • A. A case of bilateral asymmetric incomplete no. 4 facial clefts. The cleft lip on the left side is not at the typical location of an ordinary cleft lip. The left medial canthus is also slightly downward

displaced. The reason that surgery is not performed on the cheek on the left side is because the deformity is so mild that it is not worthwhile to reposition the left medial canthus, with the resultant long paranasal scar. Hence, only the cleft lip is repaired in bilateral fashion, whereas unilateral repair is performed on the cheek. The ruler demonstrates the mirror-image position of the medial canthus on the cleft side. **B.** The ruler demonstrates the mirror-image position of the nasal floor and alar base on the cleft side. **C.** The new position of the medial canthus on the cleft side with 2 mm overcorrection.

■ Incisions

- Incision lines are marked along the margin of the nasal unit medially in a curvilinear fashion upward to the true medial canthus, then turning laterally, incorporating a triangular-shaped medially based flap on the upper eyelid.
- The incision then comes back medially to the proposed point of the new medial canthus.
- The lateral skin incision is made on the lateral cleft margin up to the medial canthus.
- The lip landmarks and incision lines are marked as regular unilateral or bilateral cleft lip repairs (**TECH FIG 2**).

TECH FIG 2 • The incision lines: the prolabial width is similar to the design of an ordinary bilateral cleft lip. The tissue lateral to the proposed philtral column is discarded. A medially based triangular flap is designed on the upper eyelid.

■ Dissection and Facial Flap Elevation

- The redundant skin is excised and discarded to avoid an unnatural-looking repaired cleft lip.
- The extent of the muscle dissection is similar to that in an ordinary cleft lip repair (**TECH FIG 3A–C**).
- On the midface, the laterally based cheek flap is then elevated subperiosteally with a relaxing incision on the periosteum lateral to the infraorbital neurovascular bundle (**TECH FIG 3D,E**).
 - This allows the cheek flap to be advanced medially up to the lateral edge of the nasal flap and down to the philtral column.
- The muscle layer of the cheek is then separated from the skin for a few millimeters to facilitate the muscle approximation in later steps.
- The medially based nasal flap (in unilateral lesions) and the alar base are raised off the underlying nasal cartilages and the frontal process of the maxilla to allow downward rotation of the shortened oculolabial tissue. In patients with bilateral lesions, the nasal flap is based superiorly as there are

incisions along both sides of the nose.

- The nasalis muscle is identified and dissected from the overlying skin in a sheet for about 5 mm for later muscle reorientation (**TECH FIG 3F**).
- In cases of complete no. 3 facial clefts, the nasal lining and the lining of the eyelid are repaired by local turnover mucosal flaps between the nasal and cheek incisions (**TECH FIG 3G**).

TECH FIG 3 • A. The incision of the lip part. The excessive tissue on the right lateral lip is preserved initially as it might be needed later for lengthening of the cheek region. **B.** The incision and dissection of the lip part is similar to a bilateral cleft lip repair. **C.** The extent of the muscle dissection on the lateral lip. **D.** Subperiosteal dissection of the cheek flap. **E.** A relaxing incision is made lateral to the infraorbital neurovascular bundle (*arrow*) to achieve adequate mobilization of the cheek tissue. **F.** The dissection of the nasalis muscle (*arrow*) in the nasal flap. **G.** Turnover flap along the cleft margin for reconstruction of the nasal lining.

■ Eyelid Correction

- Attention is then turned to the lower eyelid.
- After dissection and freeing of the displaced facial musculature, the subperiosteal mobilization of the laterally based cheek flap is extended superiorly up to and including the inferior orbital rim (**TECH FIG 4A,B**).
- Usually, it is not very difficult to identify the remnant of the medial canthal tendon (**TECH FIG 4C**).

- The overlying lower eyelid tissue incorporating the tarsus and the attached conjunctiva are then transposed medially.
- If necessary, a lateral canthotomy may be required to facilitate the medial movement of the lower eyelid, correction of the coloboma, and reconstruction of the lower eyelid (**TECH FIG 4D**).

TECH FIG 4 • **A.** Dissection along the infraorbital rim. **B.** Dissection into the orbital floor. **C.** The remnant of the medial canthal tendon (upper forceps). **D.** The remnant of the medial canthal tendon and the lower eyelid are advanced medially and superiorly to the proposed position of the medial canthus.

■ Repositioning the Facial Musculature

- The lateral cheek flap is then advanced medially.
- A medial canthopexy is performed by transnasal wiring or directly suturing

to the local periosteum using the medial edge of the tarsal plate and the remnant of the medial canthal tendon (**TECH FIG 5A**).

- This will ensure adequate support for the lower eyelid.
- The orbicularis oculi muscle of the lower eyelid is identified and apposed to the superior limb of the newly created medial canthus (**TECH FIG 5B**).
 - It should be re-emphasized that this medial canthopexy always needs some overcorrection in cephalic direction for about 2 mm; otherwise, the position of the canthus will always be lower than its peer in the noncleft side after skin closure.
- The nasal complex of the medially or superiorly based nasal flap is then rotated downward matching the alar base on the noncleft side to achieve adequate oculoalar distance in unilateral lesions.
- For bilateral clefts, the positions of the alar bases are determined by the position of the columellar base (**TECH FIG 5C,D**).
- Repositioning of the remaining facial musculature, in particular the nasalis and the muscles of facial expression, is then performed.
- The sutures are placed more superiorly on the nasal muscles and more inferiorly on the cheek muscles to achieve a “rotation advancement” (**TECH FIG 5E**).
- With the redundant skin of the upper lip lateral to the philtral edge previously excised, a rotation-advancement repair of the cleft lip is performed in unilateral cases and bilateral cheiloplasty is performed for patients with bilateral lesions (**TECH FIG 5F**).
- The orbicularis oris is reconstituted and reapposed to the muscle bundle on the noncleft side.
- The medial edge of the cheek flap is then sutured to the lateral edge of the nasal flap with the suture line placed along the junction of the facial units.
- The medially based upper eyelid flap can be trimmed at this moment if the oculo-oral or oculonasal distance can be restored without difficulty, or can be placed as a small triangular flap on the lower eyelid under the medial canthus to further lengthen the oculo-oral or oculonasal distance, or to break down the straight line scar and to prevent possible postoperative scar contracture¹⁴ (**TECH FIG 5G**).
- Repositioning the facial musculature and placing the suture line along the junction of facial units results in a more natural facial expression and therefore a better aesthetic result.

TECH FIG 5 • A. The medial canthal tendon is sutured to the periosteum of the new position of the medial canthus using 4-0 Prolene suture. **B.** The orbicularis oculi muscle of the lower eyelid is identified and apposed to the superior limb of the newly created medial canthus. **C.** The alar base position on the cleft side is determined by the base of columella. **D.** Excision of the excessive skin on the cheek flap helps for the lengthening of the oculonasal distance. **E.** Approximation of the muscle layer in cheek flap and nasal flap. The sutures are placed higher on the nasal flap and lower on the cheek flap to achieve the “rotation-advancement” movement. **F.** The lateral lips are approximated to the prolabium. The marking under the right nasal floor shows the skin needs to be excised for further downward movement of the nasal floor. The medially based upper eyelid flap is still preserved at this moment. **G.** The medially based upper eyelid flap is excised finally as the length of the oculonasal distance is adequate after reconstruction. The suture lines are placed along the junction of the facial units.

PEARLS AND PITFALLS

Markings

- Precise marking of the anatomic position of the medial canthus and alar base

Incision

- Make an incision along the cleft to raise the laterally based cheek flap and medially/superiorly based nasal flap.
- The incision line of the lip is similar to ordinary cleft lip repair with special care not to preserve the redundant tissue lateral to the philtral column.

	■ Design a medially based flap on the upper eyelid.
Dissection	■ Extensive subperiosteal dissection of the cheek tissue lateral to the infraorbital foramen ■ Extensive perichondrial dissection of the nasalis muscle
Reconstruction	■ Local turnover flaps for the lining of eyelid and nose ■ Midface rotation advancement with approximation of the cheek muscles and nasalis muscles ■ Medial canthopexy in an overcorrected position ■ Adjust the lower eyelid by the medial-based flap from the upper eyelid.
Aesthetic concerns	■ Placement of the suture lines along the junction of the facial subunits ■ Design for overcorrection of the oculonasal or oculo-oral distance (eg, move the proposed medial canthus upward and alar base downward)

POSTOPERATIVE CARE

- The postoperative care is similar to that used for primary cleft lip repair.
- The airway maintenance and chest care are as important as that in any patient who received general anesthesia.
- The routine facial wound care in Chang Gung Craniofacial Center is to use normal saline wet dressing changed with the frequency of every 4 hours.
- This wound care can be replaced by local antibiotic ointment if the wounds are clean without much discharge.

OUTCOMES

- A retrospective review of the outcomes of surgical repair for rare facial clefts in Chang Gung Craniofacial Center was done in the early 2000s. The study reviewed the facial clefts over a period of 25 years.
- Among the 41 different Tessier craniofacial clefts seen, most (17 patients) were Tessier no. 3 and no. 4 clefts. Patients could be roughly divided into two groups: a group of eight patients treated by the traditional Z-plasty principles and second group of nine patients treated with the rotation-advancement technique described. Of these nine patients, five had Tessier no. 3 clefts and four had no. 4 clefts. Seven were primary cases, and the other two were secondary or tertiary revisions.
- None of the patients in the Z-plasty group had a satisfactory result in terms

of scar quality, color matching, or natural facial expression. The cases in the rotation-advancement group, while their medial canthus and alar base might not be well repositioned, still had much better results in their scar and facial expression⁶ (**FIGS 8** and **9**).

FIG 8 • An example of the midface rotation advancement on a Tessier no. 3 facial cleft. Before operation (**A**) and at 13 years old (**B** and **C**).

FIG 9 • An example of the midface rotation advancement on a Tessier no. 4 facial cleft. Before operation **(A)** and at 17 years old **(B–D)**.

COMPLICATIONS

- Postoperative bleeding
- Wound infection
- Wound dehiscence
- Hypertrophic scar formation
- Undercorrection with malposition of the medial canthus or alar base and persistent ectropion of lower eyelid.

17 Tessier 7—Macrostomia Repair

CHAPTER

Patrick A. Gerety and Scott P. Bartlett

DEFINITION

- Macrostomia—enlarged oral aperture—related clefting of the oral commissure
- Tessier 7 cleft—lateral (transverse) facial cleft from the oral commissure to the zygomaticotemporal suture
- Cheilion—anatomic name for commissure point
- Commissuroplasty—recreation of oral commissure

ANATOMY¹

- Oral commissure (**FIG 1**)
 - Position
 - Normal position: at a vertical line dropped from the medial limbus (some variability)
 - Shape
 - Normal shape: The upper and lower lip vermilion comes to sharp corner.
 - Macrostomic commissure: Oblique angle, gaping at rest, round with smile
- Tessier 7 cleft resulting in macrostomia
 - Variable in presentation—may be slightly wider oral commissure or severe cleft of skin, subcutaneous tissue, muscle, and bone
 - Trajectory—the cleft occurs along a line from the oral commissure to the zygomaticotemporal suture.

FIG 1 • Lateral facial cleft creates discontinuity of the orbicularis oris at the oral commissure. This in turn affects the location and insertion of the zygomaticus, risorius, and depressor anguli oris muscles.

■ Affected structures

- Commissure—laterally positioned, anatomically abnormal (ie, made of cleft tissue [lighter in color than normal vermilion])
- Orbicularis oris—interrupted and malinserted. The superior and inferior limbs contribute to the appearance of the lips on the macrostomic side (see **FIG 1**).

PATHOGENESIS

- Development of normal facial anatomy is dependent upon early first and second branchial arch embryology.
- The maxillary and mandibular prominences normally fuse in early embryologic development (weeks 4–6) forming the normal cheeks and lips.
- Stapedial artery is the blood supply before the external carotid system has developed.
- Stapedial disruption starves all tissue types—skin, fat, muscle, and bone.

- Macrostomia results as a presumed failure of this process.
- Interruption of embryologic development along the “orotragal” line can affect the oral commissure, muscles of mastication, muscles of facial expression, mandible, maxilla, and auricle.
- Isolated macrostomia is a disorder of the first branchial arch only.

NATURAL HISTORY²

- Incidence: rare, 1 in 225 000 live births
- Unilateral 80%, bilateral 20%
- As with cleft lip, the left side appears to be more commonly affected.
- May be associated with syndromes including the following:
 - Hemifacial microsomia
 - Including Goldenhar syndrome and variants of oculoauriculovertebral spectrum
 - May account for as many as 25% of macrostomia patients
 - Treacher Collins syndrome
 - Auriculocondylar syndrome
- Tessier 7: the most common of the rare craniofacial clefts (5%–14%)

PATIENT HISTORY AND PHYSICAL FINDINGS

- Laterally displaced oral commissure
- Clefted/interrupted orbicularis oris
 - Oral incompetence may be encountered.
 - Gaping oral commissure in repose related to cleft orbicularis oris muscle
- The cleft margin is demarcated. It does not contain normal lip elements (eg, white roll, dry vermilion), but it is mucosalized. The normal dark red vermilion can be seen to transition into a lighter colored cleft vermilion.
- Spectrum of the cleft³
 - Minor form—1 to 2 cm in length ending medial to the anterior border of the masseter muscle
 - Major form—cleft ends lateral to the medial border of the masseter. It may terminate at the tragus or at the tonsillar pillar with disruption of superficial and deep structures.
- The commissure is blunted/effaced, and when a baby with macrostomia cries, the commissural angle of an open mouth is more oblique than the normally formed commissure—this is thought to be related to disruption of the normally

intact orbicularis ring.

- Associated anomalies
 - Preauricular tags
 - Microtia/ear anomaly
 - Mandibular hypoplasia
 - Condylar abnormality
 - Zygomatic arch abnormality
 - Hearing loss

IMAGING

- 3D craniofacial CT—if bony involvement is suspected, this may be obtained to evaluate anatomy.

SURGICAL MANAGEMENT

- Trilaminar repair—repair of oral mucosal, orbicularis muscle, and facial skin
- Repair consists of
 - Excision of abnormal cleft margin tissue (mucosa)
 - Repair/repositioning of orbicularis muscle
 - Recreation of the oral commissure
 - Rearrangement of the cutaneous scar to avoid deforming contracture
- Repair types (external cutaneous scar):
 - Straight line
 - Z-plasty
 - W-plasty

Preoperative Planning

- Standard facial photos should be obtained preoperatively including repose and animated (smiling) if possible.
- Appropriate expectations should be created with the parents in terms of realistic commissure appearance and the risk of scar hypertrophy/contracture.
- Evaluation for other anomalies and comorbidities with specialist consultation or multidisciplinary team as necessary
- 3D CT scan if cleft is thought to involve skeletal structures
- Timing—as with cleft lip surgery, macrostomia repair may be done early in life. It is also reasonable to delay until late infancy if there is minimal functional or feeding issue. Late treatment reported in the literature is a function of later age at presentation and is usually not due to planned delay in

treatment.

Positioning (FIG 2)

- Nasal endotracheal tube allows unobstructed/distorted view of the mouth during surgery.
- Many groups use oral RAE intubation and midline taping that does not alter the lower lip (tape mesentery on chin).

Approach

- Determination of commissure position is most critical.
 - This can be mirrored from the contralateral lip in unilateral cases.
 - In bilateral cases, there are several considerations:
 - The cleft demarcation can be fairly obvious—normally demarcates with clefted tissue.
 - The normal position of the commissure lies below a vertical line that is dropped from the medial limbus. This can be marked.
 - Normative measures have been proposed for this use. However, these measures are highly variable and are not suitable for individual patient use.

FIG 2 • Securing of the endotracheal tube in order to avoid lip and commissure distortion. Tegaderm is used to keep tape secure in a wet (Betadine) environment. (Note the commonly associated preauricular skin tags.)

TECHNIQUES

■ Vermilion-Shifted Commissuroplasty With Optional Cutaneous Z-Plasty (Kaplan Technique)

- The senior author's (SPB) preferred technique for macrostomia repair was inspired by the work of Ernest Kaplan⁴ and expanded upon by John Mulliken.⁵
- This repair uses mucosalized flaps to avoid scars directly within the commissure.

Markings

- Markings are performed using methylene blue ink and a pen point instrument.
- Important landmarks include the following:
 - Normal commissure (if present)
 - Peak of right and left Cupid's bow
 - Lower lip cutaneous midline
 - Vertical registration marks are also drawn above and below the normal and proposed commissures as reference (**TECH FIG 1**).
- In unilateral cases, the distance from the Cupid's bow peak to the normal commissure is reflected onto the cleft-side white roll of the upper lip.
 - The distance from the lower lip midline to the oral commissure is then reflected onto the white roll of the lower lip at the cleft commissure.
 - Because it is difficult to measure these distances around the curvature of the lip, it is often easier to create a vertical registration marking on the unaffected side and to then reflect that measurement to the affected side (see **TECH FIG 1**).

TECH FIG 1 • Landmarks for unilateral macrostomia repair: (c) normal commissure, (c') upper and lower lip cleft commissure, (cb) peak of Cupid's bow on each side of the upper lip, (LLM) lower lip midline. The distance from c to the ipsilateral cb and to LLM is measured. These measurements are then reflected to the macrostomic side. Vertical registration marks can allow for more accurate measurements and design.

- In bilateral cases, the medial limbus is taken as the landmark for which to position the commissures upon repair.
- Vertical registration lines are drawn down from the medial limbus.

Design (see **TECH FIG 2**)

- The commissure points are decided upon and tattooed with methylene blue

at the upper and lower lip white roll.

- A vermilion flap is designed from either the upper or lower lip. The flap begins medial to the commissure (c) point on the chosen lip. It is rectangular in shape.
 - This flap will become the new mucosal commissure and importantly keep suture line outside of the commissure.
- The cutaneous margin of the cleft is marked—this tissue represents cleft/mucosal tissue that will be reflected initially into the mouth. Some tissue will be used for oral closure, and some will be discarded.
- On the lip (upper or lower) that will receive the vermilion flap, the incision at the cutaneous vermilion junction will also end medial to the commissure (c) point.
- The area of dissection is conservatively infiltrated with epinephrine-containing solution.

Dissection and Orbicularis Repair

- The markings are incised.
- The vermilion flap is incised and raised.
- The cleft mucosal tissue is freed and reflected intraorally with dissection to include the deep surface of the orbicularis muscles.

TECH FIG 2 • Repair design. A vermilion flap is designed that will bridge the new commissure in order to keep a scar line out of the repair. The cleft margin tissue shown with a *dotted line* is elevated and raised intraorally. The vermilion flap begins medial to the commissure point and will be inset medial to the commissure point on the recipient lip.

- The mal-positioned fibers of the orbicularis oris of the upper and lower lip are dissected free.
- The muscles are repaired in an overlapping fashion if enough muscle bulk exists for such a repair. Otherwise, they can be repaired end to end (**TECH FIG 3**).
- Repair is done with 3-0 or 4-0 Vicryl suture.

Commissuroplasty and Skin Closure

- The tattooed (c) points are united with a buried dermal suture.
- The vermilion flap is then inset with 4-0 chromic recreating the commissure.

TECH FIG 3 • Orbicularis repair in macrostomia. **A.** Overlapping. **B.** end to end.

- Excess mucosa intraorally may be trimmed, and intraoral closure is completed with 4-0 chromic.
- Deep fascia is closed in the lateral skin wound.
- A small midincision Z-plasty is designed for transverse lengthening if needed.
- Skin closure is performed with buried deep dermal 5-0 Monocryl or with simple fast-absorbing gut sutures.
- Dermabond is used for the cutaneous incision with one Steri-Strip placed along the nasolabial fold.
- Franco et al. applied a similar concept, carrying the vermilion and orbicularis as a unit across the cleft to recreate the commissure (**TECH FIG 4**).⁶

TECH FIG 4 • **A.** Vermilion flap inset after repair. **B.** Repaired macrostomia. The use of Z-plasty for cutaneous closure is an intraoperative decision.

■ Modifications of the Cutaneous Scar (TECH FIG 5)

- Linear scar closure with no modification⁷
- Z-plasty closure along the nasolabial fold⁴
- W-plasty modification of the cutaneous scar for aggressive nonlinearization⁸

TECH FIG 5 • Cutaneous closure of macrostomia. **A.** Straight line. **B.** Z-plasty. **C.** W-plasty.

Endotracheal tube	■ If using an oral tube, the taping/securing must be closely guided by the surgeon. This ensures minimal commissure distortion and a secure tube throughout the case.
Local anesthesia	■ It is important to judiciously use epinephrine-containing local anesthetic. It helps keep the field relatively bloodless, but one must allow sufficient time for the effect to occur (ie, 5+ minutes). It is also important to not tumesce and thus distort the tissues.
Medial limbus	■ A critical landmark for commissure location in bilateral macrostomia cases.
Scar hypertrophy	■ Preoperative counseling, a proactive postoperative scar management program, and an established timeline for scar interventions are critical.
Lateralization and rounding	■ Many macrostomia repairs will result in lateral migration of the commissuroplasty and a nonanatomic commissure.

POSTOPERATIVE CARE

- For 3 to 4 weeks postoperatively, the scar is treated with massage and silicone gel.
- Hypertrophic scar may be treated with steroid injection at 3 to 6 months.
- Scar revision may be necessary 1 year or more postoperatively.

OUTCOMES

- Excellent, symmetric results can be achieved. Rogers and Mulliken (2007) reported on 13 patients⁵:
 - Age at surgery 11 months, follow-up 10.3 years
 - Commissure position averaged 1 mm difference
 - No lateral commissure migration

COMPLICATIONS

- Dehiscence
- Scar contracture with lateral commissure migration
- Scar hypertrophy

Section V: Cutaneous Lesions

18 Tissue Expansion for Congenital Nevus

CHAPTER

Lee W. T. Alkureishi and Bruce S. Bauer

DEFINITION

- Congenital melanocytic nevi (CMN) are the most common congenital nevi.
- They are usually present at birth, but “tardive” CMN may arise within the first 2 years of life.
- CMN range from millimeter size to giant, covering the majority of the body.
- Implications include risk of melanoma, CNS involvement, and disfigurement.

PATHOGENESIS

- CMN result in a disturbance of neural crest cell migration between the 5th and 24th weeks of gestation, producing ectopic rests of immature melanocytes.¹
- This is thought to be related to mutations in NRAS and, to a lesser extent, BRAF oncogenes.²
- Nevus cells can extend deep into the subcutaneous tissue, fascia, muscle, and/or periosteum (rare).
- Involvement of the leptomeninges or brain parenchyma is known as neurocutaneous melanosis (NCM).
- Histologic findings specific to CMN include cell clustering, a round shape, and location within eccrine ducts, in follicular epithelium or blood vessels, and in deeper tissues.

NATURAL HISTORY

Malignancy Risk

- Malignant melanoma may arise within the nevus or in extracutaneous locations, most commonly the CNS.
- Population heterogeneity, lack of standardized descriptors, and multiple treatment modalities lead to difficulty ascertaining the true melanoma risk in CMN.
- Earlier studies reported lifetime risk of up to 40%.
- More recent studies suggest much lower lifetime risk: less than 5% for all patients with large CMN and under 2% for smaller lesions.³
- Factors associated with increased melanoma risk include larger nevus size, truncal location, and multiple satellite lesions. The greatest risk may be extracutaneous.
- Risk of melanoma arising within a small CMN prior to puberty is extremely low.
- The same is not true for large (LCMN) and giant (GCMN) lesions; 50% of those developing malignancy do so within the first 3 years of life.⁴
- To date, there has not been a confirmed case of melanoma arising within a satellite lesion.
- Other tumors associated with CMN include lipomas, schwannomas, sarcomas, malignant cellular blue nevus, and undifferentiated spindle cell neoplasms.
- Reduction of the risk of melanoma is still viewed as a valid medical indication for excision.

NEURO CUTANEOUS MELANOSIS AND IMAGING

- The presence of nevus cells within the leptomeninges, brain, or spinal column is NCM.
- Symptoms can range from none to progressive, severe neurologic impairment, hydrocephalus, seizures, and death.
- Problems arise from either benign proliferation of nevus cells blocking cerebrospinal fluid flow or malignant degeneration.
- Exact incidence is unknown but thought to be around 5%.
 - Approximately 5% of these patients will be symptomatic, the vast majority developing symptoms before age 3.
- Prognosis of symptomatic NCM is poor, with over 90% dying within 3 years of diagnosis.
- The highest risk of NCM is thought to be in patients with LCMN of the

posterior midline or greater than 20 satellite nevi. These patients should be strongly considered for MRI screening.⁵

- MRI demonstrates shortening of the T1 relaxation time and, less commonly, T2 relaxation time.
- For best sensitivity, MRI is recommended prior to 4 months of age due to the lack of myelinization in the newborn.
- In patients with symptomatic NCM, aggressive management of the cutaneous lesion needs to be decided on a case-by-case basis and is generally not recommended. This does not hold true for asymptomatic patients, in which the prognosis is more favorable.

DIFFERENTIAL DIAGNOSIS

- Blue nevus
- Mongolian spot
- Nevus of Ota/Ito
- Café au lait spot
- Nevus spilus
- Sebaceous nevus
- Spitz nevus

Classification

- Several classification schemes have been proposed, most of which use the projected adult size (PAS) of the nevus as the main feature.
- PAS is calculated by multiplying the largest diameter of the nevus in infancy by a factor that which varies by anatomical region (Table 1).
- Large CMN are considered as any nevus with a PAS of greater than 20 cm or greater than 2% of total body surface area.

Table 1 Projected Adult Size (PAS) of Congenital Nevi in Infancy (Data from Krengel et al., 2012)

Body Area	Projected Adult Size (PAS) Multiplication Factor
Head	1.7×
Neck, trunk, buttocks, arms	2.8×
Legs	3.3×

- The most inclusive classification system is that recently described by Krengel et al.⁶ (Table 2).

Nevus Distribution

- CMN may arise anywhere on the body.
- Large and giant CMN often occur in recognizable patterns or distributions.
- Size and extent of involvement vary considerably between patients.
- Extensive nevi often involve multiple adjacent areas and/or cross the midline.
- Commonly encountered distributions include:
 - Scalp, forehead, root of nose, and upper eyelid
 - Face: cheek, nose, and lower eyelid
 - Trunk (posterior, anterior, or circumferential “bathing trunk” nevus)
 - Upper extremity (sleevelike distribution)
 - Lower extremity (as part of bathing trunk or isolated lower extremity)

FIG 1 • Facial nevus, involving the unilateral cheek and abutting the lower eyelid.

- The surgical management of these patients is tailored to the location of nevus, extent of involvement, and presence of adjacent normal skin.
 - However, we describe common techniques and principles, many of which may be applicable for the management of nevi in any location.
- The example provided in this chapter focuses on a nevus involving the

unilateral cheek and lower eyelid (**FIG 1**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients are often seen in infancy.
- Any changes in appearance of the lesion over time should be noted.

Table 2 Proposed New Classification of Congenital Melanocytic Nevi

CMN parameter	Terminology	Definition
CMN projected adult size	"Small CMN" "Medium CMN" "M1" "M2" "Large CMN" "L1" "L2" "Giant CMN" "G1" "G2" "Multiple medium CMN"	<1.5 1.5–10 cm 10–20 cm >20–30 cm >30–40 cm >40–60 cm >60 cm ≥3 medium CMN <i>without a single, predominant CMN</i>
CMN localization ^a CMN of the head CMN of the trunk CMN of the extremities No. of satellite nevi ^b Additional morphologic characteristics	"Face," "scalp" "Neck," "shoulder," "upper back," "middle back," "lower back," "breast/chest," "abdomen," "flank," "gluteal region," "genital region" "Upper arm," "forearm," "hand," "thigh," "lower leg," "foot" "S0" "S1" "S2" "S3" "C0," "C1," "C2" "R0," "R1," "R2" "N0," "N1," "N2" "H0," "H1," "H2"	No satellites 50 satellites 20–50 satellites None, moderate, marked color heterogeneity None, moderate, marked surface rugosity None, scattered, extensive dermal or subcutaneous nodules None, notable, marked hypertrichosis ("hairiness")

^aOne or more of these locations should be used to describe *preponderant* area of

involvement.

^bRefers to number of satellites within the first year of life; in case this number is not available, actual number should be mentioned.

CMN, Congenital melanocytic nevi.

Reprinted from Krengel S, Scope A, Dusza SW, et al. New recommendations for the

categorization of cutaneous features of congenital melanocytic nevi. *J Am Acad Dermatol*.

2013;68(3):441-451, with permission from Elsevier.

- Nevus size and location and the presence of multiple satellite nevi should prompt screening for NCM.
- A family history of melanoma should be elicited.
- Potential psychological problems associated with this diagnosis should not be underestimated, especially in older children and adolescents.
 - Emotional, behavioral, or social problems are present in 30%.
- On initial examination, the extent of the nevus should be noted, including involvement of critical structures and any areas of adjacent normal skin for treatment planning.
- Serial examinations every 3 to 6 months are recommended.
- Darker pigmented areas or raised nodules may represent neural nevus rather than malignancy.
- Selective biopsy can be used to exclude malignancy for any suspicious areas but is rarely indicated if excision and reconstruction are already contemplated.

NONOPERATIVE MANAGEMENT

- Treatment of CMN is most often surgical, with excision and reconstruction. Other modalities include dermabrasion, curettage, and laser therapy. Some cases are best approached with observation alone.
- Some giant nevi are so extensive as to preclude excision, and regular follow-up by a pediatric dermatologist is recommended.
- Although many LCMN are amenable to surgical excision and reconstruction, the surgical experience needed for successful surgical management is not readily available in many areas of the world.

Dermabrasion and Curettage

- Dermabrasion and curettage are used to reduce, but not eliminate, the number

of nevus cells within a lesion.

- Dermabrasion is used to abrade away the surface cells within the epidermis and upper reticular dermis.
- Curettage separates the cells at a natural cleavage plane between superficial and deep dermis.
- Both techniques are best performed within the first 15 days of life.
- Lightening of the nevus can be successful initially, but this is variable and the lesion may tend to redarken over time. Follow-up may also show marked hypertrichosis.⁷
- These techniques are theoretically less effective at reducing malignancy risk, due to persistence of nevus cells at deeper levels. Resultant scarring may also complicate surveillance of the lesion. Cases have been reported of melanoma arising within the field of previous dermabrasion.⁸

Laser

- Laser remains an attractive option, potentially reducing the level of pigmentation without scarring.
- Lasers used in the treatment of CMN include ruby, Q-switched, Er:YAG, and carbon dioxide, either alone or in combination with Nd:YAG or Q-switched ruby lasers.
- Serial treatments are required, and scarring can occur with aggressive treatment or improper settings.
- Hypo- and hyperpigmentation may also occur and may be transient or permanent.
- The disadvantages of laser treatment are similar to those of dermabrasion/curettage and include continued malignancy risk, scarring, difficulties with surveillance, and redarkening of the lesion over time.
- Despite their current limitations, nonoperative modalities do offer some benefits in certain situations.
 - For example, lightening a thin lesion on the eyelid
- Improvements in laser technology will likely continue to improve outcomes with this modality, expanding its usefulness in the future.

SURGICAL MANAGEMENT

- Surgical excision allows complete removal of nevus cells in the involved skin and subcutaneous tissue.

- Excision generally includes all tissue above the level of the deep fascia.
- Although skin grafts have been used for resurfacing, the mainstay of reconstruction is with tissue expansion.
 - Replacement of the excised tissue with similar thickness normal tissue (skin and subcutaneous fat) provides the most functional and aesthetic outcome.
- Early excision is recommended.
- Procedures can be safely carried out starting as early as 6 months of age.
- Those parents with concerns about multiple procedures under the age of 1 can delay initial surgery until after the first birthday (though in expander patients started at 6 months, the maximum additional surgeries under 1 year are only two).

FIRST STAGE: PLACEMENT OF TISSUE EXPANDER(S)

Preoperative Planning

- Treatment begins with the evaluation of the nevus extent and adjacent areas of unaffected skin amenable to placement of tissue expander(s).
- For lesions affecting the cheek and lower eyelid, a single expander placed in the lower cheek/neck is often appropriate.⁹
 - The size of expander chosen is dependent on the size of lesion, availability of adjacent unaffected tissue, and anticipated size of flap required.
 - For many infants, a 70- to 90-cc expander is the largest that can be placed.
 - With adequate expansion, the resultant flap can be designed to place incisions to lie less conspicuously at the junction of adjacent aesthetic subunits.
- For more extensive nevi involving the temporal forehead, scalp, or upper eyelid, an additional expander may be required in the forehead region.
- For nevus involving large portions of the nose, an expanded forehead flap based on the supraorbital or supratrochlear artery is the best option and must be done as the first expansion.
- The expanded forehead flap places the final scar along the brow rather than midforehead.
- For extensive forehead and nasal lesions, subsequent expansion and flaps can be safely done without risk to the prior nasal flap.
- Prior to surgery, the family undergoes extensive teaching regarding the procedures, postoperative care, technique of tissue expansion, and anticipated timing of the next stage.

- In the majority of cases requiring multiple rounds of expansion, each round is separated by at least 4 months.

Positioning

- The patient is placed supine on the operating table.
- A roll is placed under the upper back and shoulders, ensuring adequate neck extension.
 - This is especially important, as it is frequently necessary to dissect the pocket for the expander past the level of the mandible and into the neck.
- General anesthesia is administered via an oral RAE endotracheal tube.
 - Care is taken to ensure this is secured exactly in the midline, avoiding asymmetric distortion of the facial anatomy.
- If the nevus is hypertrichotic, a clipper is used to ensure the margins are clearly visible for incision planning.
- The face, scalp, neck, and shoulders are cleaned with surgical soap and saline, and drapes are applied.

Approach

- Considerations in planning the incision:
 - The length of the incision should be adequate to facilitate dissection of the pocket and insertion of the expander, but no longer than necessary.
 - The incision is generally placed within the nevus, at the inferior margin. By staying within the nevus, all healthy uninvolved skin is preserved.
 - In selected cases with a narrow inferior “finger” of nevus flanked by adjacent normal skin, it may be preferable to place the incision farther into the substance of the nevus. Although this will result in the nevus being partially expanded, it achieves maximal expansion of the normal skin.
 - In patients with fine hairs along the border of the nevus, it may be preferable to place the incision just beyond the margin of the nevus, as those hairs may complicate cleaning the incision and increase the likelihood of secondary infection.
- The dimensions of the pocket for the expander are measured and marked on the skin.
 - The pocket measures 1 cm greater than the expander in both dimensions.

TECHNIQUES

- The incision line is infiltrated with lidocaine 1% and epinephrine 1:200 000.
- Incision is made with a 15c blade and deepened to the level of the subcutaneous fat.
 - Care is taken to stay perpendicular, avoiding unnecessary undermining of the nevus.
- With Iris scissors, the supra-SMAS plane is carefully developed under direct vision.
- Once the plane is established, the skin flap may be laid flat, and the majority of the remaining pocket can be dissected using the scissors without direct visualization.
 - The scissor blades can be seen on the surface of the skin, and the depth of the dissection can be accurately gauged by paying close attention to the tips.
 - This approach helps to minimize trauma to the thin skin flap.
- Particular care must be taken in the region just anterior to the mandibular angle, where the marginal mandibular nerve may be encountered. In addition, the facial artery and vein can potentially cause troublesome bleeding in this region. The depth of dissection is critical in this region, to avoid injury to the nerve below while maintaining a robust skin flap of sufficient thickness above. Of note is that the marginal mandibular nerve lies deep to the platysma, and if dissection remains superficial to the SMAS plane, the marginal mandibular nerve is spared.
- The dissection is carried over the mandible into the neck, to the extent of the pocket previously marked.
- The pocket is packed lightly with gauze for hemostasis, and attention is then turned to the expander.
- The location for the expander port is chosen and the length of tubing adjusted as needed.
 - A remote internal port is used in all cases.
 - The port should be placed over firm underlying structures to facilitate palpation.
 - The port should be placed through a limited tunnel to minimize risk of displacement or flipping.

- For lower face expanders, the temporal scalp is a typical location for the port.
- A narrow tunnel for the port is created using scissor dissection, a malleable retractor of similar width to the port, a urethral sound, or a combination of all.
 - The width of the tunnel should be limited to the diameter of the port, to prevent migration of the expander along the tunnel.
- A narrow gauge suction drain is placed into the expander pocket through a separate stab incision (19-G butterfly IV, reconfigured as a drain).
- The expander is filled with a volume of injectable saline dependent on size and location of the expander, filling enough to ensure a smooth contour.
- The port is generally inserted into the pocket first and guided into position with finger pressure or using a malleable retractor.
- The expander is rolled lengthwise, forming a thin tube with the edges rolled underneath, which is then easily inserted into the pocket.
 - Once the majority of the expander is within the pocket, it can be unfurled to lie flat.
 - Care should be taken to ensure that there are no folds present on the top surface of the expander, particularly in the face where the overlying skin flap can be very thin.
- The skin is closed in layers with interrupted 5-0 clear nylon for the dermal layer and a running 5-0 Prolene over this.
- The expander port is then accessed, and an additional small volume of saline may be injected.
 - The skin is observed and palpated during injection, to avoid overfilling.
 - In general, a total of approximately 15 cc is well tolerated at this stage.
- The site is cleaned and dressed with bacitracin, Xeroform gauze, gauze fluffs, and a loose SurgiNet dressing.
 - A tight dressing should be avoided over the expander, as this can easily compromise the skin flap.

PEARLS AND PITFALLS

Physical findings

- The appearance of CMN is widely variable, ranging from relatively inconspicuous flat, pale hairless nevi to dark or variably

	pigmented, highly rugous/nodular nevi with hypertrichosis.
Technique	■ The use of Bovie electrocautery is limited, so as not to cause thermal injury in the dissection of thin, potentially tenuous skin flaps for the expander pocket. ■ A 19-gauge “butterfly needle” makes for an excellent drain. The end of the tubing is perforated and placed into the pocket through a separate stab incision. Standard blood draw vacutainers can be used to provide suction. ■ Avoiding folds and points on the superficial surface of the expander is key to minimizing the risk of skin breakdown and subsequent exposure of the expander.
Postoperative	■ The key to successful expansion is to pay close attention to the skin’s response to the fill. Aiming for a specified volume with each expansion will inevitably lead to problems. ■ The first postplacement expander fill is typically 8–10 days postoperatively, and expansion then continues weekly. This can increase to q4-5 days in select cases if the overlying skin relaxes sufficiently.

POSTOPERATIVE CARE

- Patients can generally go home on the day of surgery, depending on parent comfort.
- Dressings are changed twice daily, keeping the incision and skin flap moisturized with Aquaphor or similar dressing.
- Drains are usually removed within 3 to 7 days, after which the dressing may be minimal.
 - Postoperative antibiotics are continued until the drains are removed.
- Expansion is begun at days 8 to 10.
 - The first expansion is performed under supervision in the clinic.
 - Subsequent expansions may be carried out at home or in the clinic depending on parents’ preference.
- Parents are advised not to focus on a target volume for each fill but to assess the skin’s response to the additional volume.
 - Skin turgor
 - Blanching indicates excessive fill, and some volume should be removed.
 - Expansion should not be painful; discomfort indicates excessive fill.
- Expansion is usually carried out weekly, unless the child has symptoms of upper respiratory infection or fever of unknown origin.

- The frequency may be increased to q4-5 days in some cases.
- Total expansion time may range from 8 to 12 weeks.
- Expansion may continue up until a few days before surgery (**FIG 2**).

SECOND STAGE: EXCISION OF NEVUS WITH EXPANDED FLAP RECONSTRUCTION

Preoperative Planning

- The planning of the second stage procedure begins prior to the first stage.
 - Position of the expander should take into account the anticipated flap design.
 - When advancing tissue from the neck to the cheek area, a transposition design is optimal.
 - This allows greater flap movement and helps align scars optimally along the junction between aesthetic subunits.
- The surgeon must decide whether to base the transposition flap laterally (most common) or medially.
 - The size and location of the lesion help to determine this.
 - Where early experience involved use of medially based flaps, the inferolaterally based flaps used today allow better reconstruction of the aesthetic unit with less risk of downward traction on the lower eyelid.
 - Smaller lateral based cheek lesions may be reconstructed with expanded inferomedially based flaps.
 - Even with expansion, the size of nevus that can be excised laterally without undue traction on the eyelid or oral commissure is limited.

Positioning

- Positioning, prepping, and draping are the same as for stage I.

FIG 2 • A. Fully expanded lower cheek/neck tissue expander **(B)** ready for nevus excision and expanded flap reconstruction.

Approach

- The initial incision is planned to facilitate removal of the expander.
- The incision is marked around the inferior extent of the nevus, as before, but outside the nevus margin (**FIG 3**).
- If the nevus margins are very light or indistinct, it is better to err on the side of preserving potentially uninvolved skin. Any areas that subsequently darken may be removed at the time of later scar revision or satellite removal.
- In cases where the nevus margin is clear, a surgical margin of 1 to 2 mm is adequate.
- Similarly, if only partial excision is planned/possible, then it is often better to keep as much of the scars within nevus tissue that will later be excised. In these cases, placing the incision within the nevus margin is advisable.

FIG 3 • Marking the incision for expander removal. The extent of the inferior extension of the incision is determined after expander removal.

- For laterally based flaps, the incision is often carried inferiorly in the line of the nasolabial fold, to facilitate flap transposition. However, the extent of this inferior incision is determined later, after expander removal.

TECHNIQUES

■ Incision

- Incision is made with a 15c blade through the skin and deepened through the subcutaneous fat with electrocautery to the level of the expander capsule.
- The expander pocket is entered through the capsule.
 - The capsule is extremely important for the vascular supply of the flap. As such, it is important not to undercut the flap at this stage, as excessive removal of capsule can jeopardize the vascularity of the flap's extremes.
- The incision and deeper dissection are continued inferiorly for a short distance in the line of the nasolabial fold and marionette line, and once a large enough window has been created, the expander is removed.
 - The tubing connecting the expander to its port is cut, and the port is left in situ for now. Removal is often easier later in the procedure.
- The expander pocket is now fully accessible. The skin flap can be placed under moderate tension in the direction of the planned transposition, and

limited release of the capsule with electrocautery facilitates greater transposition without creating undue tension on the closure (**TECH FIG 1A**).

- Care must be taken not to perform too much capsular release, as the importance of its vascular contribution cannot be overemphasized.
- The extent of the dissection is a delicate balance between facilitating movement and preserving the viability of the flap.
- With the capsule is released, the skin becomes the limiting factor in achieving the desired transposition.
- Options for skin release include extending the incision further down the nasolabial fold/melomental fold, backcutting into the flap, or both (**TECH FIG 1B**).
- The type of extended incision or backcuts used is dependent on the extent and location of the nevus and the extent and location of uninvolved adjacent skin.
- Small triangles of uninvolved skin adjacent to the flap margins can often be used to fill in the defects created by backcuts.

TECH FIG 1 • A. Limited release of the capsule with the skin flap on tension allows greater transposition of the flap without undue tension. However, the extent of release must be balanced with preserving as much vascular supply as possible. **B.** Options for skin release include extending the incision further down the nasolabial/melomental fold, backcutting into the flap, or both. **C.** The transposed flap, which covers the entire cheek at this stage.

- These small areas would otherwise be discarded, as they are covered by the transposed/advanced flap.
- Their interposition serves to allow a greater backcut, relieving tension and affording greater movement.
- Careful design of these small flaps can also break up the linear scar and/or place portions of the incision in the relaxed skin tension lines.
- The flap is again placed on moderate tension, and the extent of transposition is evaluated. At this point, the flap will often cover the entire cheek to the level of the lid crease, nose-cheek junction, and nasolabial fold (**TECH FIG 1C**).
- It can be helpful to temporarily tack the flap in place under moderate tension, allowing the areas of tension to be fully assessed.

- Further movement of the flap may be needed in the following situations:
 - Nevus involvement of the root of the nose or nasal sidewall
 - Nevus involvement of the upper lip
 - In these cases, the inferior and medial-most extent of the flap can reliably reach these extremes. The additional backcuts into the flap should be designed to allow this.
 - For all backcuts and incisions within the substance of the expanded flap, care should be taken to include sufficient capsule with the smaller or more tenuous of the created flaps. This helps to maximize vascular supply within the flap, particularly the venous drainage.
 - This may require beveling of the incisions in some cases, capturing more of the subcutaneous tissue and particularly the capsule.
 - Upon flap transposition, a dog-ear of excess tissue will be apparent in the temporal region.
 - This is excised above the level of the lateral canthus, allowing secure flap fixation high enough to prevent the development of ectropion due to flap descent.
 - At this stage, the port for the expander is close to the level of dissection, and removal is relatively easy.
-

■ Excision

- Once the flap release is completed, the extent of nevus excision can be decided.
 - The defect created by excision should allow reconstruction without excessive tension on the flap.
 - In general, the superior extent of excision should be the lower eyelid-cheek junction. When the nevus also involves the lower eyelid, the very thin eyelid skin is best reconstructed with a full-thickness skin graft at a later stage.
 - The excision of nevus in this area should be delayed until the cheek flap is fully secured both medially and laterally.
 - If possible, the triangle of skin immediately lateral to the alar-cheek junction should be preserved if not involved by nevus.
 - This allows the scar in the nasolabial groove to terminate at the nose-cheek junction rather than the alar base.

- The nevus is excised at the level of the superficial musculoaponeurotic system (SMAS), and hemostasis is achieved with bipolar cautery (**TECH FIG 2**).
- This can be performed in stages, securing the flap to the deeper tissues at several points as the dissection progresses superiorly.
- This allows the most accurate determination of the flap's reach, ensuring that the distal portion of the flap is not placed under excessive tension due to overly aggressive nevus excision.

TECH FIG 2 • The nevus is excised at the level of the superficial musculoaponeurotic system (SMAS).

■ Suturing

- Deep sutures can be used to serve dual purposes.
 - Suturing the deeper tissue of the flap to the underlying periosteum with clear nylon can help prevent later downward migration of the flap.
 - Suturing the more superficial tissue of the flap to deeper tissues can help recreate anatomical grooves or folds (eg, at the alar base–cheek junction). At this site, through-and-through sutures into the nasal cavity are often used. Based on the requirements of the specific case, the flap can be anchored to the periosteum along the pyriform. On the flap side, the depth of the suture is dependent on how much of a groove is desired. Placing the

suture higher (eg, grabbing part of the dermis) will create a deeper groove. The flap may also be anchored through and through into the nasal cavity at the level of the alar-cheek junction, using an absorbable suture.

- Key sites for deep suture fixation of the transposed flap:
 - Lateral orbital rim
 - Medial orbital rim
 - Nose-cheek junction
 - Alar base–cheek junction
- The remainder of the flap is inset with deep dermal sutures.
 - 5-0 clear nylon is used in areas with sufficient flap thickness.
 - 5-0 Monocryl (Ethicon, Inc., Somerville, NJ) is used in areas of thinner overlying tissue.
- It is of utmost importance to include the expander capsule along the entire border of the flap in the closure of the deep layer and in the placement of dermal sutures.
 - This ensures that the capsule is “unfolded,” maximizing the venous return. Folds or wrinkles in the capsule due to incomplete or incorrect inset can significantly affect the viability of the flap.
 - The flap may often appear congested until the capsule is fully unfolded.
- The final excision and inset along the nasolabial groove and melomental fold are not carried out until the above flap inset is near complete in order to avoid traction on the upper lip and commissure where final nevus excision will be required, leaving the lip intentionally “long” and the commissure pushed medially. This allows final excision to achieve symmetry.
 - With scar contraction, there is a tendency for the ipsilateral nostril to be pulled downward and the lip to be pulled upward.
 - The inset of the flap is designed to compensate for this, with the nostril slightly higher and the lip lower compared with the contralateral side (**TECH FIG 3**).

TECH FIG 3 • Flap inset is designed to compensate for subsequent scar contraction, with the ipsilateral nostril slightly higher and the lip lower than the contralateral side.

■ Closure

- A single butterfly drain is placed through a separate stab incision and secured as before.
- Skin closure is with running 6-0 chromic and 7-0 Vicryl (Ethicon, Inc., Somerville, NJ) sutures (**TECH FIG 4**).

TECH FIG 4 • The completed reconstruction. **A,B.** On-

table. **C.** Mature postoperative result, prior to excision of the small areas of residual nevus.

PEARLS AND PITFALLS

Technique

- Transposition of the flap should be completed before completely excising the lesion, ensuring adequate flap coverage.
- The lower cheek/neck expanded flap can reach as far as the root of the nose or upper lip when needed.
- Deep suture fixation at several points is key to preventing downward migration of the flap and resultant ectropion.
- Through-and-through sutures at the alar base–cheek junction can help recreate the natural groove in this area.
- The thin skin of the lower eyelid cannot be satisfactorily reconstructed with a cheek flap and is best addressed with full-thickness skin graft at a subsequent procedure.

Postoperative

- Postoperative care is essentially the same as for the first stage.

POSTOPERATIVE CARE

- The face is cleaned and dressed with bacitracin, Vaseline gauze, gauze fluffs, and a loose SurgiNet dressing.
- Ophthalmic bacitracin should be used around the eye.
- Patients may go home on the day of surgery, depending on parent comfort.
- Postoperative regimen is unchanged from the first stage.

OUTCOMES

- In the authors' hands, expanded flap reconstruction with a laterally based lower face/neck flap provides the most pleasing results for this type of lesion.
- The quality and thickness of the expanded flap match that of the uninvolved skin.
- The contour of the lower cheek and neck is superior to that achieved with a medially based flap.
- Deep suture fixation is effective in preventing later ectropion with vertical descent of the flap tissue.

- For nevi involving the lower eyelid, a further stage is generally required.
 - This allows time for the flap to settle into its final position and any small adjustments to be made.
 - Medial or lateral canthopexy can be utilized to address any scar contraction or minor flap descent.
 - If further deep fixation is required at the lateral orbital rim, a permanent suture can be placed through a drill hole in the bone of the orbital rim.
 - The eyelid nevus is then excised and reconstructed with a full-thickness skin graft.
- When excision of nevus involves expanded flap reconstruction of the forehead and scalp as well as neck, the reconstruction should be sequenced to address the scalp, forehead, and cheek; the cheek should be reconstructed last.
 - The cheek excision and reconstruction can commence once the forehead flap is inset in final position. Skin closure may be performed at the same time.

COMPLICATIONS

- Infection during expansion can occur and is more common in the neck compared with other sites in the head and neck.
 - Infection can usually be managed with antibiotics, occasionally for the remainder of the expansion process.
 - Severe infection requiring removal of the expander is rare.¹⁰
- Extrusion of the expander is rare.
 - Maintaining a flap of sufficient thickness minimizes this risk.
 - In older children where a 250-cc expander may be used, the most important part of expander placement is ensuring that the dissected pocket is large enough for the expander to be placed with minimal folds or irregular points.
- The main complication of the second stage is vascular compromise of the expanded flap.
 - The increased vascularity afforded by expansion lowers this risk.
 - Flap compromise is always partial; total flap compromise does not occur.
 - Partial flap necrosis is generally limited to the distal aspect of the flap.
 - Sloughing is most often partial thickness and manageable with local wound care.
- Infection is very rare following removal of the expander.
- With placement of scars along the junctions of aesthetic subunits, the mature scar is very good in most cases. However, problems with hypertrophic or

widened scars can occur and may require scar revision. This can often be combined with other planned procedures (eg, excision of satellite nevi).

- When there is some extension of the nevus medial and inferior to the nasolabial fold, leaving that final excision until the scars have settled allows more precise final closure and may avoid the need for later scar revision.

19 Surgical Treatment of Congenital Midline Nasal Mass

CHAPTER

Patrick A. Gerety and Scott P. Bartlett

DEFINITION

- Congenital midline nasal masses are a rare occurrence but require a thorough workup for an intracranial component, which then necessitates a transcranial resection.
- These masses typically represent one of three diagnoses: dermoid cyst, encephalocele, or glioma.
 - A nasal dermoid sinus cyst (NDSC) is lined by stratified squamous epithelium and contains dermal adnexal structures such as hair follicles and sebaceous glands. The cystic contents are sebum. If the mass has a punctum with drainage to the outside world, it is a dermoid sinus; otherwise, it is a dermoid cyst.
 - A nasal encephalocele is an extracranial protrusion of a cerebrospinal fluid (CSF)-containing dural mass. Twenty-five percent of all encephaloceles are in the nasofrontal region (sincipital). If brain matter is within the mass, this is referred to as meningoencephalocele.
 - A nasal glioma represents extracranial brain matter with no patent CSF connection.
- Intracranial extension—extension of midline nasal masses from extracranial nasal location to the anterior cranial fossa
- Transcranial approach—a combined extracranial and intracranial resection with reconstruction

ANATOMY

- Formation of a midline nasal mass results from disruption of early

embryologic processes. The exact theory of embryology responsible for the formation of transcranial nasal masses remains debated.¹ Several operating theories lend rationale to the occurrence and anatomy of these masses. Some of these theories include the prenasal space theory, the nonseparation theory, and the ectodermal inclusion theory.

- Transcranial nasal congenital masses are believed to exist for two important reasons (**FIG 1**):
 - Failure of normal regression of a transcranial embryologic structure (dural diverticulum)
 - Embryologic contact of surface and neural ectoderm
- Per one theory, a dural diverticulum from the anterior cranial fossa normally exits the cranium via the nasofrontal junction (the fonticulus (nasofrontalis) frontalis) and ends between the nasal bones and nasal soft tissues.
 - This diverticulum normally involutes and can be identified as the foramen cecum. This foramen has no contents typically but may contain a fibrous stalk.
 - If this process is disrupted, a persistent transcranial connection may be present at birth.
 - Importantly, the neural ectoderm of this diverticulum makes contact with the surface ectoderm of nasal skin. Normally, this connection also regresses. If it does not, it may pull skin elements beneath the nasal skin resulting in an NDSC.
- The transcranial connection may occur at a number of anterior cranial fossa midline structures: cribriform plate, crista galli, foramen cecum, nasofrontal junction, or any combination of these.
- Anterior cranial encephaloceles can also occur via the nasofrontal, nasoethmoidal, or naso-orbital bony junctions.

PATHOGENESIS

- The etiologic basis of this occurrence is likely multifactorial with a genetic component. Family history and multiple siblings have been identified with these masses. Midline nasal masses are not related to any known syndromes or other known congenital anomalies.
- Conceptually and for disease categorization, these masses particularly the encephalocele are related to the embryologic failure of anterior neuropore (normally embryologic day 24) during early embryologic development.

FIG 1 • Embryologic origin of congenital frontonasal masses. Early embryologic connection between the nasal space and the intracranial space may lead to the presence of the congenital nasal mass. The existence of NDSC may be related to neural and surface ectoderm, which as the diverticulum regresses may draw skin contents into a subcutaneous position and in some case maintain a transcranial connection.

- A cranial defect must be present for either of the three main masses to be seen nasally and transmitted transcranially.
- Dermoid cysts likely result from trapping of skin structures subcutaneously as the dural diverticulum involutes normally.
- Encephalocele represents a neural tube defect. Terminology varies depending

upon what the extracranial mass contains.

- Meningocele—meninges only
- Meningoencephalocele—meninges and brain matter
- Encephalocele and glioma represent neuroectodermal malformations.
- Dermoid cysts and sinuses represent a somatic (surface) ectodermal malformation.
- Intranasal gliomas and encephaloceles likely have a herniation point in the anterior cranial fossa that is more posterior (ie, posterior to the cribriform plate) as compared to masses that are seen on the nasal dorsum.

NATURAL HISTORY

- Congenital midline nasal masses are rare with an approximate incidence of 1 in 30 000 live births.
- These masses, particularly encephaloceles, occur in higher rates in Asia (Western incidence, 1 in 35 000; Asian incidence, 1 in 5000).
- NDSC—midline nasal cysts represent 3% to 12% of head and neck dermoid cysts.²
 - Intracranial extension of midline nasal dermoids has been found to be common among these masses on the order of 25% to 45% of cases.
- Encephalocele—approximately 80% are occipital and 20% frontonasal (sincipital).³
- Glioma
 - Approximately 15% have a transcranial connection; thus, nasal resection without intracranial exclusion can lead to CSF leak and meningitis.
 - 3:1 male predominance⁴
 - Sixty percent are extranasal, 30% are intranasal, and 10% are mixed.
- There is a reported association with other nonspecific congenital abnormalities (often quoted as approximately 40%). However, several series have not shown the same association. A transcranial midline nasal mass may occur in isolation.
- Risk of meningitis—with good soft tissue coverage and no sinus punctum, patients are likely at low risk of developing a meningeal infection even in the presence of intracranial CSF connection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Visible and palpable midline nasal mass (**FIG 2**)
- May occur from the columella to the radix but most commonly along the nasal

dorsum

- Wide nasal bridge
- Hypertelorism—this may be true hypertelorism with total orbital widening or more commonly in this case interorbital hypertelorism with widening of only the medial orbital wall.
- May be present in 70% of encephalocele patients
- Normal interorbital distance increases from approximately 18 mm in infancy to 25 to 30 mm in adulthood.

FIG 2 • Physical appearance of congenital midline nasal mass. **A.** Dermoid sinus with pathognomonic hairs from punctum. NDSC may also present as subcutaneous firm mass with no punctum. **B.** Nasal glioma with pathognomonic telangiectasia. This may be indistinguishable from a nasal dermoid without a dermal sinus. **C.** Nasal encephalocele with bluish hue, large size, hypertelorism, and positive fluid wave on exam.

- NDSC are firm, round masses.
 - NDSC may present with a punctum. The punctum may contain hair, which is a pathognomonic sign of the diagnosis.
 - If a punctum is present, patients are more likely to present with infection.
- Gliomas are firm, round masses.
 - Surface telangiectasia is present and this is pathognomonic.
 - May be extranasal, intranasal, or both
 - Does not transilluminate or change in size
 - Intranasal glioma may cause nasal airway obstruction or nasolacrimal dysfunction. Airway obstruction is particularly problematic in neonates/infants who are obligate nasal breathers.
- Encephalocele may occur through one of three sutures (junctions): nasofrontal, nasoethmoidal, and naso-orbital.

- Often appear blue in color
- Transillumination is pathognomonic because of CSF content.
- Size change with crying may occur (Valsalva).
- Size change may also be elicited by compression of the internal jugular veins (Furstenberg sign).
- Patients may present with CSF leak or frank meningitis.
- The cranial exit point has been found to be fairly variable and may occur at the nasofrontal suture but also through other cranial bone junction points.
- This can be difficult to differentiate on physical examination.

IMAGING

- Because of the occurrence of transcranial extension, there should be a low threshold for obtaining cross-sectional imaging of congenital midline nasal masses.
- In general, both a maxillofacial CT scan and brain MRI are obtained.
- CT scan provides a better examination of bony distortion and bony relationships.
- MRI is thought to be more sensitive and specific for transcranial soft tissue extension and for brain structural examination.⁵
- Typical imaging findings (**FIG 3**):
 - Interorbital distance—widened
 - Frontonasal cranial defect
 - Nasal bone—displaced and angulated
 - Bifid crista galli
- Tissue diagnosis via biopsy is contraindicated in these masses before a noninvasive, cross-sectional imaging workup has been performed.

FIG 3 • A,B. MRIs reveal extra and intra components (*arrows*) in a 1-year-old girl with glabellar mass. **C,D.** Midline encephalocele is apparent in AP and lateral CT scans in a 4-month-old girl.

DIFFERENTIAL DIAGNOSIS

- The following are other diagnoses outside of NDSC, encephalocele, and glioma, which may occur on the nasal dorsum congenitally.⁶
 - Hemangioma/vascular malformation
 - Teratoma is pathologically distinct and contains all three layers, including

endoderm, which is not present in NDSC.

- Lipoma
- Neurofibroma is often seen in concert with other neurofibromatosis cutaneous findings.

SURGICAL MANAGEMENT

Preoperative Planning

- Multidisciplinary collaboration
 - Plastic surgery
 - Neurosurgery
 - Ophthalmology—preoperative exam (interorbital, intercanthal, and interpupillary distances as well as eye movements), postoperative management of strabismus, and nasolacrimal management
- CT and MRI
- Hydrocephalus should be managed preoperatively by neurosurgery possibly with ventriculoperitoneal (VP) shunt before definitive correction (only pertains to encephalocele).
- Timing of surgery should be for at least late infancy (8 to 12 months) to allow better perioperative physiology and maturation of bone, which aids osteotomies and fixation.
- Transfusion and postoperative critical care are required.
- Computer-based 3D surgical planning may play a role in hypertelorism correction in the future.

Positioning

- Resection and reconstruction are done in a supine position.

Approach

- **FIG 4** is a decision-making algorithm for resection choice.
- Extracranial approach
 - Transnasal excision
 - Reduction of excess frontonasal skin
 - Open rhinoplasty—has been demonstrated when skin excess is minimal and there is no punctum. This can avoid dorsal nasal scar.
 - Intranasal—excision may be done through nares or open rhinoplasty approach if the mass is intranasal (more often with glioma).

- Intracranial
 - Frontal craniotomy
 - Limited craniotomy
 - Endoscopic minimally invasive approach
 - Immediate interorbital hypertelorism correction
- Dual approach
 - Extracranial
 - Intracranial
- Aims
 - Divide nasal and meningeal tissue and seal them apart.
 - Correct nasal soft tissue excess as needed.
 - Repair cranial base dural and bony defects.
 - Move medial orbits/medial canthi into normoteloric position if necessary.

FIG 4 • Algorithm for choice of resection technique.

TECHNIQUES

- **Resection of Transcranial NDSC (“The Keystone Technique”)**
 - Havlik et al. are responsible for describing and popularizing this technique.⁷

Nasal Approach/Frozen Biopsy

- In the case of dermoids with uncertain transcranial component, the mass is dissected down to its stalk. The stalk is biopsied for frozen section.⁸
- If it does not contain dermal contents, then the procedure is terminated with extracranial excision only.
- If dermal elements are present, an intracranial approach is followed (**TECH FIG 1**).

TECH FIG 1 • External approach to midline nasal mass. This approach is combined with an intracranial approach when imaging, or intraoperative frozen biopsy confirms intracranial extension. **A.** Elliptical design for excising this nasal NDSC. **B.** The cyst and its stalk have been dissected down to the nasal bones, and a biopsy can be done at the deepest point.

Incisions, Dissection, and Craniotomy

- Bicoronal incision is designed at a symmetric point in the hairline just above the helical root. This is designed as a zigzag pattern to decrease visibility.
- Dorsonasal—a conservative elliptical skin excision is designed for nasal skin reduction and as access for dissection of the mass.
- An anterior scalp flap is raised in the areolar subgaleal plane (**TECH FIG**

2A).

- The pericranium should be carefully preserved.
- Upon approaching the orbits and nasofrontal junction, a plan for raising a subpericranial flap and subperiosteal dissection should be formulated.
- A large pericranial flap should be marked and raised to keep it in continuity with the scalp. This also allows full subperiosteal dissection of the orbits.
- The medial orbits and frontonasal defect edges are dissected subperiosteally with an elevator.
- A bifrontal craniotomy approximately 1cm above the supraorbital bandeau is performed by neurosurgery (**TECH FIG 2B**).
- The frontal lobes can be dissected and retracted to reveal the cranial base and the intracranial/dural extension of the mass (**TECH FIG 2C**).

Keystone Osteotomy and Dermal Sinus Excision

- To visualize the dermoid sinus tract, the frontonasal junction is osteotomized and removed (**TECH FIG 3**).
- This is done via vertical parasagittal osteotomies.
- This can be done to take only midline frontal bone or to include the nasal bones.
- Both approaches require reconstruction of the frontonasal junction or of the keystone area depending upon what is osteotomized.

TECH FIG 2 • Transcranial approach to nasal dermoid. **A.** Design and reflection of coronal scalp flap. **B.** Design of frontal craniotomy and limited bandeau (so-called keystone approach—frontonasal osteotomy). **C.** Keystone osteotomy of frontonasal junction in order to access the transcranial component of the mass.

- The dermal sinus tract is resected from its dural connection following visualization.
- The NDSC, glioma, or redundant meningeal tissue is excised.
- At the site of the mass that is resected, a careful dural repair is performed by neurosurgery. Dural substitute is used as needed.

Bandeau/Frontal Bone Repair

- The keystone portion of the frontal bone is fixated back in place with resorbable hardware in infants and rigid hardware in older children.

TECH FIG 3 • View of the transcranial component of the mass after frontal craniotomy.

- Fixation of the frontal bone should not compress or strangle the pericranial flap.
- Sizeable full-thickness cranial defects such as large bur holes can be filled with cranial bone shavings/particulate.
- A subcutaneous, closed suction drain is placed and the scalp is closed.

Cranial Base Repair and Seal

- If a bony defect is present in the cranial base, it should be treated with full or split calvarial bone graft (**TECH FIG 4A**). This bone is fashioned to the size and shape of the defect but not typically fixated.
- The pericranial flap harvested during scalp dissection (**TECH FIG 4B**) is then placed over the graft covering the cranial base.
- If possible, sutures are used to secure the flap. Fibrin glue is used to seal the edges of the flap (**TECH FIG 4C**).
- The pericranial flap acts to provide vascularized barrier both for the dural repair and the cranial base bone defect.

Completion

- The frontal sinus is not an issue in infants as the sinuses have not yet

developed.

- In patients with delayed presentation and treatment, the frontal sinuses should be cranialized and the frontonasal duct should be obliterated with cautery and bone graft.
- The nasal skin redundancy is evaluated and additional skin is removed if necessary. The nasal skin is closed.

TECH FIG 4 • Seal of the anterior cranial base after transcranial resection. **A.** Bone graft (either full- or split-thickness calvarium) is placed in the cranial base defect. **B.** A pericranial flap is planned preoperatively for coronal scalp flap dissection. **C.** The pericranial flap is placed over the bone graft, and fibrin tissue sealant is used along with sutures to ensure a watertight seal.

■ Medial Orbit Composite Unit Translocation

(MOCUT) Procedure

- This technique has been described and popularized by Boonvisut et al. for immediate hypertelorism repair in nasal encephalocele.⁹

Approach and Dissection

- The same coronal incision and bifrontal craniotomy as described for Resection of Transcranial NDSC above is utilized.
- The nose can be opened via either a vertical incision on the dorsum or through a conservatively designed vertical ellipse.
- Subperiosteal dissection is performed at the supraorbital bandeau into the orbits.
- Orbital dissection is limited to the medial aspects of each orbit between the supraorbital notches. Care is taken to keep the medial canthal tendon insertion intact.
- Careful subperiosteal dissection is used to ensure that the orbital and soft tissues are moved in concert in an uninterrupted fashion.
- The subperiosteal dissection is carried medially to the bone edges at the frontonasal defect.

Osteotomies, Resection, and Reconstruction

- Medial orbital wall is cut vertically from the craniotomy at the level of the supraorbital notch down to the inferior orbital rim (**TECH FIG 5A**).
- Via the nasal incision, a transverse osteotomy is performed from the piriform aperture to the inferior orbital rim to free the composite medial orbital unit.
- In the midline, bone will need to be removed from the medial orbital unit to establish the final interorbital distance.
 - This distance is planned preoperatively using a CT scan.
- Osteotomies are performed with a combination of conventional osteotomy, reciprocating saw, and ultrasonic scalpel.

TECH FIG 5 • Encephalocele resection with transcranial approach and immediate hypertelorism correction. **A.** Bifrontal craniotomy is performed. Laterally vertical osteotomies are planned to descend from just medial to the infraorbital notch. A variable bony resection at the midline will be performed to allow medialization of the orbit and canthal units. The inferior horizontal osteotomy may be completed through the nasal incision. **B.** The medial orbit composite unit technique (MOCUT) can be seen here to immediately produce hypertelorism correction.

- Completion of the osteotomies mobilizes the orbital units allowing for improved exposure.
- The mass, typically an encephalocele with this approach, should be dissected free from its surroundings.
 - This is done via the nasal incision and the frontal craniotomy.
- Dural repair and cranial base/frontal sinus repair are as described above.
- The medial orbital units are joined at the midline with fixation (**TECH FIG 5B**).
 - This is typically done with a 30-gauge wire but may also be done using suture, permanent plates, or resorbable plates and screws.
- Transverse bony gaps at the supraorbital bandeau that have been created through orbital medialization should be treated with fixated interposition calvarial bone graft.

- Any disruption of the nasal cartilages to bone or of the nasofrontal junction should be repaired with suture.
- Redundant nasal skin should be conservatively resected. The nasal skin is closed.
- Some have argued for more complex nasal skin flaps. Our preference is for nasal skin revision at a second stage if necessary.

■ Endoscopic Excision of Intranasal Glioma

- The approach to intranasal gliomas also includes an external rhinoplasty approach and a lateral rhinotomy approach.¹⁰ These specific approaches will not be discussed here.
 - In general, this approach has been used by those who practice endoscopic surgery and skull base approaches.
 - Many have argued that with evidence of transcranial extension, a traditional craniotomy should be performed to separate the nasal-intracranial connection. Others have demonstrated that intranasal glioma with intracranial extension can be successfully excised endoscopically, thereby avoiding craniotomy.
- An angled endoscope is introduced intranasally to visualize the mass (**TECH FIG 6**).
- Electrocautery is used to incise the nasal mucosa along the mass.
- Retraction and blunt dissection define the mass.
- After defining the stalk, it is divided using electrocautery and the mass is removed.
- The base is examined for CSF leak. If necessary, it may be oversewn. Fibrin tissue sealant may also be used to ensure a seal.
- The nasal mucosa is closed with simple sutures.
- The affected nasal passage is packed. Nasal packing is removed in the early postoperative period.

TECH FIG 6 • Excision of intranasal mass. **A.** Endoscopic appearance of purely intranasal glioma. **B.** An endoscope may be used to visualize and aid excision of intranasal glioma. Endoscopic approaches to the cranial base are also well described.

PEARLS AND PITFALLS

Biopsy	■ Congenital nasal masses, particularly those occurring at or near the midline, should not be biopsied for diagnosis. Biopsy can lead to CSF leak and ascending/meningeal infection.
Radiologic evaluation	■ Congenital nasal masses should be evaluated radiographically. This often includes both a CT scan and MRI.
VP shunt	■ Decompression by neurosurgery in the setting of a large or growing encephalocele can allow surgery to be delayed until the patient is a better candidate for surgery.
Age at surgery	■ Timing of treatment, particularly with large lesions and encephaloceles, is a balance between the risk of

infection/meningitis/family stress and the safety of surgery/quality of bone for reconstruction. We recommend waiting until late infancy if there are no other time-sensitive factors.

Intracranial seal

- Transcranial approach requires careful reconstruction of the cranial base defect including bone grafting, pericranial flap, and fibrin glue seal.

POSTOPERATIVE CARE

- Pediatric ICU is mandatory with expected hospital stay of 5 to 7 days.
- Neurologic monitoring
- Routine labs for bleeding and infection
- Monitoring of nasal and drain output for CSF leak—the drain should be in place for at least 5 days.
- Close outpatient monitoring for the development of CSF leak, meningitis, and hydrocephalus
- Secondary nasal scar revision is often necessary.

OUTCOMES

- Complications
 - In these rare conditions, most case series are small.
 - Minor complications in any transcranial approach with nasal-intracranial communication should be expected to be moderate to high.
 - Catastrophic complications should be rare.
- Aesthetic outcome
 - Disruption of nasal growth and form is a high risk.
 - Revision of nasal scar/form and nasal reconstruction with rib graft should be expected.
 - Second hypertelorism correction may be necessary.

COMPLICATIONS

- CSF leak
- Meningitis
- Death
- Scar hypertrophy
- Residual hypertelorism
- Residual nasal deformity and skin excess
 - May require re-excision, local tissue rearrangement, onlay grafting of the

nasal dorsum, and formal rhinoplasty at maturity

Section VI: Soft Tissue Masses

20 Surgery of Neurofibromatosis in the Pediatric Patient

CHAPTER

McKay McKinnon

DEFINITION

- Patients with cutaneous neurofibromatosis (NF), the most common of the myriad of phenotypic manifestations of the disease (and Von Recklinghausen's original case reports), can usually expect permanent relief of individual lesions by full-thickness excision. For those patients with so-called plexiform NF and/or malignant peripheral nerve sheath tumors (MPNST), the puzzlement of a permanent treatment (medical or surgical) has remained largely unsolved for most patients.
- For well over a century, the textbook recommendation for children with NF1 plexiform tumors has been to defer surgery until after puberty or until serious morbidity is evident. When surgery has been deemed necessary, it has most often been a superficial resection of the tumor, commonly referred to as "debulking." Subsequent recurrence of tumor has led to a default strategy of withholding surgery for pediatric patients, based upon fear of iatrogenic injury to normal structures, uncontrollable hemorrhage, and perceived inability to achieve permanent tumor removal.
- Over the past 30 years, the author has observed that radical resection of plexiform tumors in adults has resulted in permanent "nonrecurrence" of nearly all tumors, even those over 50 kg and some MPNST.¹ Despite a higher

propensity for active tumor growth in children and adolescents, it seemed logical to extend the concept of radical surgical resection to pediatric patients.

ANATOMY

■ Craniofacial

- Most facial and frontotemporal scalp tumors derive from sensory branches of cranial nerve V. The ophthalmic division of the trigeminal nerve (**FIG 1A**) includes some sensory nerves that are within the musculofascial cone (annulus of Zinn) of the orbit. This area presents special risks of injury to the optic nerve and the extraocular muscles and should be avoided.

- Orbital NF is often accompanied by a defect of the sphenoid greater wing, which may permit herniation of the temporal lobe into the orbit and subsequent orbital dystopia, pulsatile exophthalmos or enophthalmos, and pressure on the globe and optic nerve. Destruction of bone, ligaments, fascia, muscle, and skin may be present.
- Tumor confined to the optic nerve (optic glioma) deserves neurosurgical management.
- Motor nerves are not intrinsically involved with NF tumor.

- NF tumors of the mandible, parotid, ear, and temporal scalp develop largely from the mandibular division of the trigeminal nerve, including the auriculotemporal nerve.

- Tumors of the neck and posterior scalp derive from upper cervical sensory nerves (C1–C4), including the occipital nerves. Lower cervical nerves (C4–C8, sensory and motor) constitute most of the brachial plexus.

■ Trunk and extremity

- Plexiform NF can exist anywhere from the spinal cord to the sensory nerve terminus in the skin, bone, or viscera (**FIG 1B**).

- Plexiform tumors most commonly appear between the deep fascia and the skin but may involve and destroy skin, muscles, bones, joints, and visceral organs. Careful dissection proximal to the tumor mass (toward their CNS origin) often reveals the specific sensory nerve origin. Large truncal lesions over time can develop paraspinal hypervascularity, which resembles an arteriovenous malformation. Scoliosis is common with posterior trunk lesions, and limb hyperplasia is common with extremity lesions.

PATHOGENESIS

- NF is an autosomal dominant condition, which can be attributed to a defect on

chromosome 17, but mosaicism can also occur. The consequential lack of neurofibromin (a tumor inhibitor) permits growth of myelinated axonal tumors in any bodily location. Tumor types are cutaneous or plexiform. So-called plexiform tumors are solid tumors, which have an obligatory angiogenic influence, similar to other solid tumors. They express multiple angiogenic and neurogenic factors. Puberty, pregnancy, and childhood growth spurts can exacerbate their growth. Tumor vascularity increases proportionate to tumor growth. Transformation of benign NF tumors into MPNST can occur in plexiform tumors. This transformation may have a direct correlation to numerical tumor cell replication events.

- Tumor vessels in NF are pathologic arteries that reveal absent media and abnormally thin adventitia. Established tumors can exhibit vascular lakes and/or nests of abnormal vessels resembling a congenital vascular malformation.

NATURAL HISTORY

- Neurofibromas, once established as plexiform tumors, do not regress spontaneously. Their growth is unpredictable and nonregular, including possible onset throughout a patient's life of new lesions. Malignant transformation is more common in truncal/extremity lesions but is also unpredictable. Café au lait cutaneous spots do not necessarily signal plexiform tumors, although they themselves represent microscopic tumor. If present at birth, plexiform tumors may have already inflicted defective tissue development of the newborn.

FIG 1 • Nerves of the orbit.

- Eventual destruction by tumor of adjacent skin, bone, and other tissue should be expected without intervention. Hyperplasia and/or fragility of bone occurs in extremity lesions. Craniofacial tumors can also produce osteoclastic or osteoblastic pathology, likely as a consequence of tumor growth rate. Tumors involving the sphenoid and orbit can cause progressive orbital dystopia, blepharoptosis, and blindness. Paraspinal tumors inflict progressive scoliosis on the growing patient.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The myriad presentations of NF tumors should not deter accurate diagnosis, even in infancy, by the observant neurologist or experienced surgeon. If doubt of the diagnosis exists, a biopsy should be performed with exception at least of the optic nerve.
- Physical findings are too numerous to justify an inclusive list, but palpable tumor, pain, and confirmatory imaging should precede surgical intervention in virtually all cases.

IMAGING

- Pediatric patients with suspicion of plexiform NF tumor should have an MRI study, preferably with and without contrast. MRI of the CNS is appropriate as an early screening measure for all NF patients, even those without known tumors. T2- and STIR-weighted images usually give the clearest depiction of NF tumor.
- MRI, especially with higher Tesla power, can frequently reveal the specific cranial or spinal nerve involved with tumor. This information (nerve mapping) should be sought out with the neuroradiologist.
- High-resolution CT scans should only be ordered when and if the patient with skeletal destruction or high risk of skeletal pathology is being evaluated preoperatively.

DIFFERENTIAL DIAGNOSIS

- NF tumors have been mistaken for vascular malformations, particularly by their hypervascular imaging on CT or MRI.
- Hyperpigmentation of NF lesions has been confused by the inexperienced physician with congenital nevus. A biopsy can readily produce the correct diagnosis.
- Most patients, even infants, with NF will present with at least three or more cutaneous lesions and/or café au lait lesions, axillary freckling, ocular Lisch nodules, or a subcutaneous plexiform mass.
- Congenital ptosis can usually be differentiated from NF-derived ptosis by detection of an orbital mass, presence of enophthalmos or exophthalmos, and by MRI findings. Rapid increase of ptosis may be associated with orbital malignancy such as rhabdomyosarcoma, for which immediate incisional or excisional biopsy is required.
- Diagnosis of MPNST or other orbital malignancies cannot be reliably made by symptoms, by imaging, or by clinical examination.

NONOPERATIVE MANAGEMENT

- This default management decision is historically common but deserves renewed challenge because it is controversial. Observation of growing NF tumors is patently nontherapeutic yet may be justified if surgery is high risk, the patient has significant comorbidity, or the tumor has not reached a level of irreversible morbidity to vital structures. The surgeon and his or her medical colleagues should be prepared to intervene to prevent irreversible morbidity,

even in young patients.

SURGICAL MANAGEMENT

- An accurate diagnosis is the sine qua non of surgical management. With plexiform NF this should include determination of the tumor nerve origin(s), the degree of vascularity, bony deformity, proximity to other vital anatomy, and degree of skin destruction. In the craniofacial tumors, accurate diagnosis also should determine presence of brain herniation into the orbit (or elsewhere), orbital dystopia, ptosis vs pseudoptosis, ophthalmic pathology, and airway and carotid/jugular risks.
- Because all NF1 tumors are caused by pathologic sensory nerves, either of brain or spinal cord origin,¹ if a total interruption of the responsible sensory nerve(s) can be achieved (eg, a Sunderland V injury), permanent nonregrowth of tumor may also be achieved.¹ Thus, surgical strategy should aim to:
 - Radically resect the plexiform tumor and identify and amputate the responsible sensory nerve(s) proximal to the tumor
 - Dissect and preserve any motor nerves in the tumor proximity
 - Undertake tumor resection even in the pediatric patient because progressive tumor growth over time equates to more complex surgery, higher risk of morbidity to normal adjacent structures and function, and possibly more risk of malignant transformation of previously benign tumors
- All techniques are subservient to the principles of reconstructive surgery. A knowledge of and adherence to principles permit the surgeon to methodically approach virtually any surgical problem to arrive at an organized plan. The reconstructive surgeon's "creed" has been summarized by Millard: "Know the ideal beautiful normal. Diagnose what is present, what is diseased, displaced, or distorted, and what is in excess. Then, guided by the normal in your mind's eye, utilize what you have to make what you want—and when possible go for even better than what would have been!"
- No clinical condition presents to the surgeon a more variable array of pathology than neurofibromatosis. The NF surgeon needs, therefore, to first make a strategy from application of principles. When the principles (such as making an accurate diagnosis, establishing priorities, making a plan and a backup plan, replacing lost tissue in kind, etc.) are applied, the surgical techniques will devolve naturally. The surgeon, much like his or her military counterpart, elucidates the goals and strategy of a military-type campaign before determining the specific technique(s) required.

Preoperative Planning

- Pertinent consultations with other specialists should be completed well prior to surgery, if feasible.
- Adequate warning to blood bank and ICU is made.

Positioning

- Most craniofacial procedures are done in the supine or lateral position with a standard OR table with a gel headrest.
- Trunk and extremity procedures are done in standard positions according to tumor site(s).

Approach

- Orbital tumors are approached via coronal, superior lid crease, and transconjunctival incisions as needed. Inferior orbital nerve (maxillary) tumors are accessed via a lower eyelid incision as in orbital floor exploration or via a nasojugal incision.
 - The surgeon should anticipate repeat procedures (ie, a subciliary incision is always a higher risk for ectropion).
- Posterior trunk tumors should be accessed via incisions that can resect not only the palpable tumor but also any feeding paraspinal sensory nerves (**FIG 2**).

FIG 2 • Spinal sensory nerves of the trunk.

TECHNIQUES

■ General Principles

- The first priority of surgery in the child with NF is resection of tumor and reconstruction of bone. Large tumor resections can be aided by cautery devices such as LigaSure, but the surgeon should be facile in vascular surgical techniques.

- Autogenous bone reconstruction is superior in virtually all cases to alloplastic reconstruction in NF, especially in the growing child.
- Because resection of cranial nerve V tumors into the cavernous sinus is dangerous (and some tumor will necessarily remain there), reconstruction of the sphenoid defect should be undertaken with a combination of bone and plate/mesh to ensure permanence of brain-orbit separation (even in the enucleated patient). Bone should face the orbit to allow possible attachment of the levator muscle origin.
- Early ptosis correction is important to avoid amblyopia, but definitive ptosis correction should be performed when the child can tolerate a nongeneral anesthetic for refinement of the correction by patient participation and tumor is not significantly present.
- When approaching a large plexiform tumor, the surgeon should begin dissection in normal tissue and proceed to identify the plane at the tumor margin. Motor nerves that are within the tumor field should be identified by direct nerve stimulation.

■ Illustrative Cases

Case 1: Inferior Orbital Nerve Tumor

- A 4-year-old girl demonstrated a rapid regrowth of a right inferior orbital nerve NF tumor 6 months following partial resection at an outside institution. The tumor was creating a vertical orbital dystopia (**TECH FIG 1A,B**).
- A resection of the inferior orbital nerve tumor from the cheek to the posterior orbit was performed via the old nasojugal vertical scar (**TECH FIG 1C,D**).
 - Alternative approaches in an unoperated patient would be a transverse lower lid incision and a separate nasolabial fold incision, or even an intraoral incision, depending on extent of tumor.
- Following resection, the marginotomy was repaired with a stainless steel wire in a corrected (inferior) reposition.
- Over the subsequent 20 years, the patient presented multiple other tumors of alternate branches of the trigeminal nerve, but not of the inferior orbital (maxillary) nerve (**TECH FIG 1E,F**).

Case 2: Hypogastric Plexiform Tumor

- A teenage girl presented a painful left hypogastric plexiform tumor

recurrence 2 years after an attempted resection at an outside hospital (**TECH FIG 2A**).

- MRI revealed the tumor extending from the skin to the deep abdominal fascia (**TECH FIG 2B**).
- Resection via an extension of the old scar included dissection and resection of the pathologic hypogastric nerve lying deep to the external oblique muscle (**TECH FIG 2C–E**).
- There had been no recurrence in 10 years of follow-up.

TECH FIG 1 • **A,B.** A 4-year-old girl with right inferior orbital nerve NF tumor 6 months after partial resection. **C,D.** A marginal osteotomy (a la Tessier) of the orbital rim allowed visualization and tumor resection in the posterior orbit to the cranial base. **E–H.** Postoperative photos.

TECH FIG 2 • A. Teenaged girl with left hypogastric plexiform tumor recurrence 2 years after attempted resection. **B.** The tumor extended from the skin to the deep abdominal fascia, as shown on MRI. **C,D.** Dissection and resection of the pathologic hypogastric nerve lying deep to the external oblique muscle. **E,F.** The result 1 year after direct wound closure.

Case 3: Breast and Chest Wall Plexiform Neurofibromatosis

- A 15-year-old girl presented with right breast and lateral chest wall plexiform NF (**TECH FIG 3A**).
- At surgery, a simultaneous resection of a right intercostal tumor and a right breast reduction/tumor resection were performed (**TECH FIG 3B,C**).
- The intercostal nerve proximal to the tumor mass was located and amputated at the rib.
- No recurrence had been observed in over 8 years of follow-up (**TECH FIG 3D**).

Case 4: Left Orbital and Mental Nerve Neurofibromatosis 1

- A 12-year-old boy presented with left orbital and mental nerve plexiform NF1 (**TECH FIG 4A,B**), severe ptosis, and pulsatile exophthalmos.
- Through a coronal, left upper eyelid, and left nasolabial incisions (**TECH FIG 4C**), the tumor was radically resected.
- Via the coronal approach (without osteotomy), the temporal lobe dura was located inside the posterior orbit and dissected from the periorbitum (**TECH FIG 4D**) and then the brain/dura was repositioned into the cranial cavity and separated from the orbit by a cranial bone graft/titanium mesh reconstruction.
- The graft/implant was placed from the orbit into the cranial cavity and held in position by autoretention.
- In the same procedure, a cranial bone graft to the orbital floor and a moderate reduction of eyelid skin excess was performed.
- Vision was preserved (**TECH FIG 4E**). The patient will need future additional floor elevation and definitive ptosis correction.

TECH FIG 3 • A. A 15-year-old girl with right breast and lateral chest wall plexiform NF. Simultaneous with resection of a right intercostal tumor (**B**), a right breast reduction/tumor resection was performed (**C**). **D.** Appearance at 8 years postoperatively.

TECH FIG 4 • A. A 12-year-old boy with left orbital and mental nerve plexiform NF1, severe ptosis, and pulsatile exophthalmos. **B.** MRI demonstrated a plexiform tumor of the superior orbit and mental nerve, a large defect of the sphenoid greater wing, and prolapse of the temporal lobe into the orbit. **C.** Markings for coronal, left upper eyelid, and left nasolabial incisions. **D.** Dissection of the temporal lobe dura inside the posterior orbit from the periorbitum via the coronal approach. **E.** Postoperative appearance.

PEARLS AND PITFALLS

Diagnosis

- The most common pitfall in NF surgery is inaccurate diagnosis.
- When recommending a tissue biopsy for definitive diagnosis, avoid

	biopsy within a highly vascular region of NF tumor or adjacent to the optic nerve. ■ Tumor heterogeneity on MRI may indicate a benign tumor adjacent to a malignant tumor.
Surgical strategy	■ The NF surgeon should avoid underestimation of tumor extent and potential hemorrhage, underdissection with nerve stimulation of motor nerves along the path of the tumor, and underestimation of a surgical strategy that anticipates tumor recurrence in young patients. ■ Lifetime surveillance by the surgeon should be assumed because the medical specialists are ill prepared to have a surgical perspective of NF. ■ The occasional NF surgeon will inevitably experience high morbidity and low patient satisfaction.
Technique	■ The surgical term “debulking” in NF1 represents a common pitfall of partial, superficial resection. Rapid recurrence of tumor normally ensues. Debulking of intraorbital tumors may, however, be justified to save vision. ■ It should be clear to the NF surgeon that vision is also at risk due to possible glaucoma, hemorrhage, tumor/brain pressure on the optic nerve, glioma of the optic nerve, severe orbital dystopia, severe ptosis (amblyopia), and palpebral incompetence.
Other specialists	■ Orthopedic surgeons, neurosurgeons, and ophthalmologists frequently treat pediatric patients with NF. ■ If limb hypertrophy or spinal scoliosis is present in conjunction with a tumor that is resectable, the plastic NF surgeon should champion primary tumor resection prior to orthopedic attempts to reduce epiphyseal growth, reconstruct joints, to correct scoliosis, or even to amputate parts. This should be intuitive as correct general surgical principle, not a pearl of wisdom. Likewise, strabismus and/or ptosis surgery should not precede tumor resection and orbital bone reconstruction.

POSTOPERATIVE CARE

- The NF surgeon should use drains freely due to the vascularity and vessel pathology of NF tumors, following extensive resections, which predispose to seroma formation.
- Suction drainage may be hazardous near the dura and may exacerbate hemorrhage near fragile-walled, residual tumor vessels.
- Since many NF surgeries overlap into other surgical specialties, the plastic NF

surgeon should include those specialists in the postoperative care but remain the captain of care and assume ultimate responsibility.

CHAPTER Vascular Anomalies

Arin K. Greene and Jeremy A. Goss

DEFINITION

- Vascular anomalies are a group of lesions that can affect any part of the vasculature.
- Lesions are divided into tumors (with dividing endothelium) and malformations (structural anomalies with minimal endothelial turnover).¹
- Eight types of vascular anomalies (four tumors and four malformations) constitute approximately 95% of lesions.

ANATOMY

- Vascular anomalies most commonly involve the integument (although they can affect any anatomical structure).
- The most common morbidity is lowered self-esteem because of a deformity.
- Lesions involving the head and neck are more likely to be problematic.

NATURAL HISTORY

- The somatic mutations responsible for most vascular anomalies recently have been identified.
- Some vascular tumors improve over time (infantile hemangioma, rapidly involuting congenital hemangioma, kaposiform hemangioendothelioma).²
- Vascular malformations slowly worsen, particularly during adolescence.
- Following treatment of vascular malformations, recurrence is common and patients often require repeated procedures.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Ninety percent of vascular anomalies can be diagnosed by history and physical

examination.

- Before considering management, the type of vascular anomaly must be identified because lesions have different natural histories and treatments.³
- The most common vascular anomalies encountered in clinical practice are (in order of frequency) pyogenic granuloma, infantile hemangioma, and capillary malformation.
- A handheld Doppler can determine whether the lesion has fast flow, which aids the diagnosis.
- Lesions with fast flow include infantile hemangioma, congenital hemangioma, kaposiform hemangioendothelioma, and arteriovenous malformation. Slow-flow anomalies are capillary malformation, lymphatic malformation, and venous malformation.

IMAGING

- Less than 10% of patients require imaging to diagnose their vascular anomaly.
- If the diagnosis is unclear by history and physical examination, ultrasound is the first-line imaging study because it is easy to perform and does not require sedation in children.
- If the diagnosis remains uncertain after ultrasonography, then MRI with contrast is obtained.
- Imaging is not required prior to resection of hemangiomas, pyogenic granulomas, or capillary malformations.
- Before operative intervention for a venous malformation, lymphatic malformation, or arteriovenous malformation, MRI typically is obtained to determine the extent of disease.

DIFFERENTIAL DIAGNOSIS

- Fibrosarcoma
- Neurofibroma
- Pilomatixoma
- Teratoma

NONOPERATIVE MANAGEMENT

- Nonoperative intervention is the mainstay of treatment for vascular anomalies; lesions are benign and often can be observed.
- Less than 10% of infantile hemangiomas require treatment. Problematic lesions during the proliferative phase can be managed with topical timolol,

corticosteroid injection, prednisone, propranolol, or rarely, resection.

- Kaposiform hemangioendothelioma is treated with vincristine or sirolimus.
- First-line intervention for problematic vascular malformations typically is nonsurgical: capillary malformation (pulsed-dye laser), venous malformation (sclerotherapy), lymphatic malformation (sclerotherapy), arteriovenous malformation (embolization).⁴⁻⁷

SURGICAL MANAGEMENT

- Operative treatment of vascular anomalies generally is performed for symptomatic patients who are not candidates or have failed nonoperative interventions.
- Residual infantile or congenital hemangiomas causing a deformity can only be improved with resection (or pulsed-dye laser for telangiectasias).
- The primary treatment of pyogenic granuloma is full-thickness skin excision or cautery (curettage, laser, and cryotherapy have a recurrence rate as high as 50%).
- Capillary malformation can cause overgrowth of tissues beneath the stain, which can be improved by resection.
- Operative intervention for venous malformation is reserved for small lesions that may be removed for cure or for a residual deformity following sclerotherapy.
- Macrocystic lymphatic malformation may have redundant skin following sclerotherapy that can be resected. Microcystic lesions are not amenable to sclerotherapy, and thus, excision often is first-line treatment.
- Arteriovenous malformations generally are removed if they remain symptomatic following embolization.

Preoperative Planning

- A critical principle is that vascular anomalies are benign and thus do not require radical resection; the scar and reconstruction should not cause a worse deformity than the appearance of the lesion.
- Vascular anomalies typically are diffuse and involve multiple tissue planes; consequently, most resections are subtotal.
- The goal of operative management is to improve the patient's symptoms by removing enough of the lesion to reduce pain, bleeding, and/or ulceration and/or improve appearance.

- Symptomatic infantile hemangiomas are best excised between 3 and 4 years of age after they have completed involution.
- If possible, resection should be postponed until the child is at least 6 months of age to reduce the anesthetic risk.
- Consideration should be given to improving deformities before 4 years of age to minimize impact on self-esteem.
- Venous, lymphatic, and arteriovenous malformations usually are removed after they have been treated with sclerotherapy or embolization; these interventions reduce the size of the lesion, decrease bleeding, create fibrosis, and facilitate the operation.

Positioning

- The table is turned 90 degrees during resection of head/neck lesions.
- To limit blood loss, the head of the bed is elevated for facial vascular anomalies.

Approach

- Intraoperative antibiotics are not administered except when resecting large lymphatic malformations because they are prone to infection.
- After marking the extent of the resection, bupivacaine with epinephrine is infused throughout the operative site to reduce blood loss and pain.
- Markings are tattooed for lesions located on the vermillion or mucosa.
- To reduce blood loss, cold epinephrine-soaked sponges can be applied to the operative field; clips may be applied to the skin edges to decrease bleeding.
- After making the incision, hemostasis should be obtained prior to proceeding with further excision to avoid significant blood loss.
- Margins are not required; the least amount of tissue as possible should be removed to achieve the operative aims.
- A pressure dressing usually is applied to minimize the risk of postoperative hemorrhage.

TECHNIQUES

■ Lenticular Excision and Linear Closure

- Most vascular anomalies act as a tissue expander, and thus, adequate skin is available to close the wound (**TECH FIG 1**).
- The majority of resections are subtotal, and thus, missing integument is rare.
- Skin grafts or local/regional flaps rarely are necessary to reconstruct an area following extirpation.
- Incisions are designed to be as inconspicuous as possible (eg, relaxed skin tension lines, hairline, etc.).
- Vascular anomalies often cause local ischemia because of insufficient oxygen delivery; consequently, interrupted rather than continuous sutures are preferred for closure.
- After resecting a facial lesion in children who are less able to tolerate suture removal, 7-0 chromic followed by cyanoacrylate glue and tape can be used.

TECH FIG 1 • A 3-year-old with an involuted infantile hemangioma managed with lenticular excision and linear closure. **A.** Preoperative appearance. **B.** Following resection. **C.** Early postoperative view.

■ Circular Excision and Purse-String Closure

- This technique is useful for round lesions to limit the length of the scar, which would be 2 to 3 times the diameter of the lesion if it was excised lenticularly (**TECH FIG 2**).^{8,9}
- Circular excision is most commonly performed for infantile hemangiomas after they have involuted, but can be used for any round skin lesion.
- Almost all procedures are conducted on the face where it is important to

limit the length of the scar; round lesions involving the trunk or extremity usually undergo lenticular excision because the linear scar is concealed and appears favorable in a relaxed skin tension line.

- A contraindication to circular excision is the scalp because there is minimal tissue laxity, a circular scar can cause visible alopecia, and it is not critical to limit the length of a scar in the scalp because it is camouflaged by hair.
- When closing the circular excision, it is important to undermine the skin edges to reduce tension; I usually prefer a Vicryl purse-string suture. After the purse-string closure, I approximate the epidermis/dermis with interrupted chromic or nylon suture (depending on the age of the patient) followed by cyanoacrylate glue and tape.
- Disadvantages of this technique are that there is an increased risk of wound dehiscence compared to linear closure and a second stage may be required to convert the circular skin into a line.

A

B

C

D

E

TECH FIG 2 • A 3-year-old with an involuted infantile hemangioma of the arm. The lesion was managed with circular excision and purse-string closure to limit the length of the scar in a visible location on the dorsum of the extremity. If the lesion was removed as an ellipse, the scar would be at least twice the diameter of the lesion. **A.** Preoperative view. **B.** Following circular resection. **C.** Purse-string closure. **D.** Appearance prior to second stage conversion of the round scar and residual telangiectasias into a line. **E.** Linear scar 6 weeks postoperatively approximates the diameter of the hemangioma that was removed.

- Approximately 50% of patients are satisfied with the round scar and do not wish to have a second procedure (the circular scar can look like an acne or chickenpox scar).
- If the circular scar is converted to a line during a second stage, its length will approximate the diameter of the original lesion.
- I wait 6 to 12 months after the circular excision before considering a second stage to convert it into a line.

■ Transverse Mucosal Resection and Linear Closure

Video p8-c021

- Vascular anomalies involving the lip often cause overgrowth and a deformity.
- Unlike malignant labial lesions, subtotal resection of benign vascular anomalies can be performed to improve the patient's appearance.
- This technique avoids the placement of a scar on the cutaneous lip (**TECH FIG 3**).
- An elliptical excision is designed along the keratinized and nonkeratinized vermillion; the markings are tattooed prior to injection of local anesthetic.
- Diseased vermillion, mucosa, submucosa, and a portion of orbicularis muscle are removed.
- The incision is closed with interrupted Vicryl and chromic suture.
- The patient is maintained on a full-liquid diet for 2 weeks.
- If the lesion regrows, it can be debulked again using the same incision.

TECH FIG 3 • Transverse mucosal resection of an involuted infantile hemangioma of the lip. **A.**

Appearance of the lesion at 3 years of age. **B.** Markings for excision. **C.** Suture line following resection. **D.** Postoperative appearance.

■ Suction-Assisted Lipectomy

- Several types of vascular anomalies are amenable to suction-assisted removal when they are located primarily in the subcutaneous plane: infantile hemangioma, capillary malformation, lymphatic malformation, and other lesions that have a significant adipose component (**TECH FIG 4**).¹⁰
- This technique allows the removal of diseased tissue without long incisions, raising skin flaps, and “open” excision, which has increased morbidity and recovery compared to liposuction.
- Stab incisions are placed in nonconspicuous areas and tumescent solution is infused (1 mL of epinephrine 1:1000, 1000 mL normal saline, 50 cc 1% lidocaine) not to exceed 35 mg/kg of lidocaine.
- Cannulas of 3 mm typically are used for the face, 4 mm for the upper extremity, and 5 mm for the trunk or lower extremity.
- The aspirate is one-half to equal the amount of tumescent that was infused.
- I usually do not use a tourniquet for extremity lesions.
- A pressure dressing is applied, and the incisions are closed loosely to allow drainage.

TECH FIG 4 • A 10-year-old female with a capillary malformation and overgrowth of her left lower

extremity managed with suction-assisted lipectomy. **A.** Preoperative appearance. **B.** Intraoperative view. **C.** Lipoaspirate. **D.** Reduced circumference of her leg postoperatively.

PEARLS AND PITFALLS

Diagnosis	■ Vascular anomalies are commonly misdiagnosed. ■ Ensure accurate diagnosis prior to operative intervention to prevent erroneous treatment.
Nonoperative management	■ First-line treatment of vascular anomalies often is not operative intervention.
Operative indications	■ Resection of vascular anomalies is indicated for small lesions or those that have failed or are not candidates for other treatments.
Hemostasis	■ Despite being vascular, significant intraoperative hemorrhage rarely occurs. ■ Blood loss can be reduced using epinephrine, elevation, cold saline gauze, cutaneous clips, and careful hemostasis with cautery.
Operative technique	■ Complete excision is not required. ■ Subtotal resection to improve symptoms typically is the goal of operative intervention. ■ Most lesions outside of the face are excised using lenticular excision and linear closure. ■ Round lesions on the face often are best removed using circular excision and purse-string closure.

POSTOPERATIVE CARE

- Individuals who have had significant resections of the head/neck spend 24 to 48 hours in the hospital and are given Decadron to reduce swelling.
- Generally, patients may shower 2 days postoperatively and the occlusive dressing and underlying Steri-Strips are allowed to “fall off.”
- Children are managed with dissolvable sutures whenever possible.
- Individuals are examined 2 to 3 weeks postoperatively and 6 to 12 months

later if a second stage is being considered.

- Incisions are reinforced with Steri-Strips and are protected from the sun for 1 year.

OUTCOMES

- Patients and their families are counseled that the area involving the vascular anomaly cannot be made to look exactly like the anatomy without the lesion.
- The best outcomes typically are obtained by improving the area of deformity with the simplest approach rather than radical resection and reconstruction.
- The most favorable results are by surgeons who have experience managing vascular anomalies.

COMPLICATIONS

- Operative management of vascular anomalies has a higher risk of perioperative hemorrhage compared to resection of other types of lesions.
- Because the tissues usually are ischemic, suture line dehiscence is more likely than removal of nonvascular lesions; interrupted sutures that are not removed too early can reduce this risk.
- Intraoperative blood loss can predispose the patient to iatrogenic injury of important structures.
- Circular excision and purse-string closure is more likely to have dehiscence than lenticular resection and linear closure.

Section VII: Pediatric Burns and Wounds

22 Functional Burn CHAPTER Reconstruction

David A. Billmire and Kim A. Bjorklund

DEFINITION

- The hallmark of burn injury in children is burn scar and burn scar contracture.
- The tendency toward hypertrophic scarring in children is a major challenge.
- Hypertrophic scars tend to develop in wounds that require greater than 3 weeks to close.
- These scars are raised, red, tight, hard, and often itchy.
- Hypertrophic scarring after burns is common and creates a wide range of cosmetic and functional problems.¹
- Contractures (inability to perform full range of motion) result from factors such as limb positioning, duration of immobilization, and muscle, soft tissue, and bony pathology.²
- Scars result in restriction in movement, particularly when they cross a joint, and increase the likelihood of contracture development.
- A similar burn injury in an adult that requires only initial resurfacing of the wound may require repeated releases and other procedures during subsequent growth and development of a child.
- Growth can be affected with restriction, distortion, and, in some cases, elongation.
- Heterotopic ossification (HO) resulting from ectopic bone formation in the soft tissue around joints can significantly affect extremity motion and function.

- Functional issues are frequently coupled with aesthetic concerns regarding loss of structures, obliteration, and distortion of normal anatomy.

ANATOMY

- Major problems tend to occur across joints and sites of active movement.
- The shoulder, elbow, and hand are most commonly affected by contractures.²

PATHOGENESIS

- In normal acute wound healing, myofibroblasts provide collagen and fibronectin deposition and aid in wound contraction over approximately 7 to 10 days.³
- However, the presence of myofibroblasts following a burn injury can result in excessive extracellular matrix deposition leading to a pathologic contracture and hypertrophic scarring.³
- Although in adults scars typically mature within 12 months, in children, the scarring diathesis may take years to resolve.

NATURAL HISTORY

- The natural history of a burn wound is to heal with re-epithelialization in superficial partial-thickness burns within 10 to 14 days.
- Deep partial-thickness or full-thickness burns heal by combination of contracture and re-epithelialization and are unlikely to heal within 14 days.
- Accordingly, burn wounds that are unlikely to re-epithelialize by 2 weeks should be treated with early operative intervention for excision and split-thickness skin grafting (STSG).
- Sheet grafts should be used in critical areas such as the face and hands.
- Less cosmetically sensitive areas can be covered by mesh graft techniques.
- We have found early sheet grafting of burn wounds (where adequate donor sites allow) to dramatically reduce the need and extent of subsequent reconstruction.
- Wound coverage is followed by an aggressive rehabilitation program with appropriate splinting and positioning in the immediate postoperative period, followed by ongoing physiotherapy, splinting, and the use of pressure garments.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Examination should focus special attention on critical areas, beginning with

the airway (neck) and eyes.

- A history of previous airway problems such as inhalation injury and need for tracheostomy should be noted.
- The presence of dry eye symptoms can be subtle in children, and coverage of the globe needs to be ascertained.
- Major joints and hands should be examined closely for restriction of growth and movement.
- Range of motion and functional limitations from scar contractures or HO should be carefully documented.
- In females, the breast buds and/or breasts should be examined to evaluate need for release or reconstruction.
- A systematic anatomic approach to catalogue affected structures is important. Complete or partial loss of limbs, digits, eyes, ears, nose, breast buds/breasts, genitalia, skull, and hair-bearing scalp should be noted.
- Previous donor sites and uninjured skin should be evaluated for future reconstructive efforts.
- Putting all of this together allows one to plan and sequence the reconstructive effort.

IMAGING AND DIAGNOSTIC TESTS

- X-rays should be obtained for significant hand burns.
- Most major joints usually do not require imaging unless the burn wound extended into the joint.
- Joints with functional limitations may benefit from x-rays to look for HO.
- Facial burns (especially those requiring face masks in a growing child) may benefit from monitoring with serial cephalograms to track facial growth and change.

NONOPERATIVE MANAGEMENT

- Nonoperative management begins in the acute phase of the burn injury.
- Many of the secondary problems in pediatric burn injuries can be avoided or lessened by the initial wound management.
- The use of sheet grafting in sensitive areas such as the head and neck and hands can dramatically reduce the need for subsequent reconstruction.
- A rehabilitation program using splinting, stretching exercises, and pressure garments can be effective in modifying the maturing burn wound and scar.

SURGICAL MANAGEMENT

- Secondary burn reconstruction ideally begins when the burn wound matures.
- Burn maturation is a lengthy process that is unpredictable and may take years in children.
- Immature burn scars are hyperemic, red, and raised and should become softer, pale, and flatter as they mature.
- While the scar is maturing, nonoperative methods previously described above should be employed.
- Certain problem areas require early intervention with the knowledge that they may need to be treated multiple times.

TECHNIQUES

■ Contracture Release

- Contractures that may interfere with growth in a child should be addressed surgically.

■ Airway, Eyes, and Lips

- The airway (neck contracture), eyes (ectropion/lagophthalmos), and contractures of the lips result in significant functional deficits including exposure keratitis, blindness, and oral dysfunction that limits eating and mouth care.⁴
- These critical areas should be treated first and early in secondary burn reconstruction (**TECH FIG 1**).

TECH FIG 1 • **A.** Planned release dart into adjacent unit. **B.** Appearance following release prior to excision of scar. **C.** Creating a template pattern for skin graft; the mouth is packed to expand the site. **D.** Full-thickness harvest site based upon template. **E.** Graft sewn in place. **F.** Stented with bolster tie over dressing.

■ Burn scar contractures

- In approaching burn scar contractures, one should start centrally and work peripherally.
- The neck, axilla, and elbow should be addressed first to allow access to the hand and provide a safe airway (**TECH FIG 2**).
- Depending on donor-site availability, numerous releases can be performed with a variety of techniques from thick-split grafts to free flaps.
- The most common reconstructive techniques include split- or full-thickness skin grafts and local flaps.

TECH FIG 2 • A. Planned incision for tight axillary region release. **B.** Appearance of axilla following release and skin grafting.

PEARLS AND PITFALLS

Contractures

- Burns unlikely to re-epithelialize by 2 weeks should be treated with early excision and split-thickness skin grafting to reduce the likelihood of hypertrophic scarring and contractures.
- Early initiation of splinting, stretching, and pressure garments can help prevent contractures and improve functional motion, especially in burn injuries across joints.

Reconstructive planning

- A systematic approach that examines all affected areas and potential donor sites should always be employed when undertaking burn reconstruction.
- Critical areas (neck, eyes, lips, and hands) are a priority and should be treated early in secondary burn reconstruction.

CHAPTER Harvesting a Skin Graft

David A. Billmire and Kim A. Bjorklund

DEFINITION

- Skin grafts are an integral part of burn reconstruction.
- Various graft options include full thickness, split thickness, allografts, cultured (engineered) skin, dermal substitutes Integra, and Alloderm.
- Full-thickness grafts consist of the entire dermal layer with the overlying epidermis.
- Split-thickness grafts include a portion of the dermis and the overlying epidermis.
- Allografts or skin substitutes are used for temporary coverage and may be biologic or synthetic.
 - Human cadaver allograft, porcine xenograft, and amniotic membrane are biologic temporary skin substitutes.¹
 - Biobrane double-layer dressing (silicone with nylon-containing collagen) and TransCyte double-layer dressing (silicone with nylon-containing neonatal fibroblasts) are examples of synthetic skin substitutes.¹
- Cultured skin such as cultured epithelial autograft (CEA) is typically grown from the patient's own cultured keratinocytes and may be coupled with an engineered dermal substrate.
- Dermal substitutes provide an engineered dermis (Integra) or allograft dermis (Alloderm) in preparation for eventual grafting with split-thickness grafts.

Advantages

- Virtually all reconstructive grafting needs can be met by either autogenous full-thickness or split-thickness grafts.

- Allografts may be used temporarily to stabilize burn wounds and create an acceptable bed.²
- Dermal substrates may allow the use of thinner split-thickness grafts in donor-limited patients.

NATURAL HISTORY

Split-Thickness Skin Grafts

- Scarring of the donor site is dependent on the site and depth of harvest, patient age, and genetic makeup.
- Once healed, the graft may exhibit dyschromia, increased scar contracture, and decreased durability.

Full-Thickness Skin Grafts

- Typically closed primarily, but in large grafts may require closure with a split-thickness graft
- Less color change and scar contracture and greater elasticity and durability

Prognosis

- Highly dependent on the quality of the wound bed and influenced by factors including vascularity, bacterial contamination, fluid collection under the graft, and shearing

ANATOMY

- Skin grafts can be harvested from virtually any part of the body.
- Physical, functional, and aesthetic characteristics of the recipient site may dictate the preferable donor site location.
- Glabrous or hairless skin can typically be harvested from areas including the sole of the foot, hypothenar eminence, retroauricular, inner upper arm, and potentially the lateral flank areas, depending on the patient.
- Full-thickness grafts can be harvested in areas with redundant skin such as the abdomen, groin, upper arms, and supraclavicular regions.

SURGICAL MANAGEMENT

Preoperative Planning

- Wound bed preparation is critical and must be debrided to healthy well-vascularized tissue. If uncertain of the readiness of the wound bed, it may be

prudent to temporize with a skin substitute following debridement.

- Donor-site choice should be matched to the recipient site for characteristics such as color, hair bearing, thickness, and texture.
- Type of graft (split or full) is chosen based upon donor availability and recipient needs.

TECHNIQUES

■ Split-Thickness Graft Harvest

- Tumescence of donor site is frequently performed to facilitate harvest, as well as reduce pain and blood loss. A Pitkin solution (1 L of Normosol with 2 mg of epinephrine [1/500 000]) and ropivacaine 0.5% (maximum dose 3 mg/kg or 10 mL spread out over the entire volume of solution needed) or other tumescent solution of choice may be used (**TECH FIG 1A,B**).
- Split grafts are typically harvested using a dermatome, which is electric, drum, or air powered (**TECH FIG 1C**).
 - For average depth split-thickness grafts, the appropriate depth of the dermatome is 12 to 15 thousandths of an inch (**TECH FIG 1D–F**).
 - For thick split-thickness grafts, the depth is set to 20 thousandths of an inch, whereas for thinner grafts, it is set around 10 thousandths of an inch.
- Manual harvesting knives such as the Humby, Watson, or Braithwaite may be used as an alternative to a dermatome. These typically require experience to ensure grafts are harvested at a uniform thickness.
- The graft may be meshed depending upon recipient site goals and availability of donor sites for harvest.
- Meshing will increase the graft surface area and allow for egress of fluid but is not cosmetically desirable.
- Grafts are typically meshed 1:1.5; however, the ratio may be increased to cover a recipient greater area.

TECH FIG 1 • A. Infiltrating Pitkin solution. **B.** Postinjection. **C.** Harvesting with powered dermatome. **D.** Stopping to check thickness. **E.** Harvested site. **F.** Dilute lidocaine with epinephrine soak.

Fixation

- Absorbable sutures, tissue glue, and staples may be used to tack the graft in place.
- The recipient bed should be healthy, well-vascularized tissue with no evidence of infection. The site should be dry to avoid a hematoma.
- Donor site can be covered with bulky dressing (**TECH FIG 2**).

TECH FIG 2 • A. Applying Kaltostat alginate dressing.
B. Bulky occlusive dressing.

■ Full-Thickness Graft Harvest

- A template or specific measurements of the recipient site defect should be used to avoid harvesting unnecessary graft.
- The full-thickness graft is typically harvested in an elliptical fashion to allow for primary closure without dog ears.
- Depth of harvest should include the epidermis and complete dermis.
- Subcutaneous tissue should be removed completely prior to inseting the graft.
- The donor site should be closed primarily in layers.
- Sutures are typically used to secure the graft to the recipient site.

Graft Dressing

- Nonadherent gauze, antibiotic ointment (Bacitracin), bulky dressing, tie over bolster, Reston Foam, and splint should be applied with either a split- or full-thickness graft.

PEARLS AND PITFALLS

Dermatomes	■ Always stop and check dermatome thickness prior to beginning split-thickness harvest.
Tumescent solution	■ Use of tumescent solution facilitates harvest by stabilizing and smoothing the surface, and reducing pain and bleeding.

Boluses

- Reston foam boluses sewn with absorbable sutures allow excellent fixation, protection, and mobility and may aid in splinting the site.

POSTOPERATIVE CARE

- The graft should remain immobilized until an initial dressing change at 5 to 7 days for split-thickness grafts and 7 to 10 days for full-thickness grafts.
- Erythema, drainage, or foul odor at the graft site should prompt a concern for graft infection and necessitate an earlier graft takedown.

24 Burned Hand Reconstruction

CHAPTER

David A. Billmire and Kim A. Bjorklund

DEFINITION

- More than 80% of all severe burns involve the hand.¹
- These injuries may be devastating with long-term functional consequences and significant morbidity.
- Burns of the pediatric hand are common and are most frequently thermal type injuries (scald, contact, or flame burns).²
- Injuries tend to occur accidentally as children explore their environment with their hands.
- However, a glove or stocking appearance to a burn, or an injury not consistent with the history, should prompt concerns for abuse.
- Hand function may be affected through tissue loss, burn scar contractures, impaired growth, and abnormal sensation.

ANATOMY

- Pediatric skin is thinner and has not yet developed the thickened palmar epidermis of an adult.³
- Dorsal skin is thin and pliable and provides less protection for underlying extensor tendons and bone.

PATHOGENESIS

- Thin dorsal skin places underlying structures at particular risk for exposure and stiffness.
- Extensor tendons are particularly at risk at the PIP joints where the central slip may attenuate or rupture with exposure, resulting in a boutonniere deformity.
- Burned hands tend to assume a position of wrist flexion, MCP hyperextension,

PIP flexion, thumb adduction, and interphalangeal hyperextension.⁴

- Early elevation, splinting, and escharotomies when indicated affect postburn edema and help prevent the development of burn contractures.
- Altered sensation and motor and nerve function may occur secondary to the burn.

NATURAL HISTORY

- Untreated or inadequately treated hand burns frequently result in contractures and long-term functional impairment.
- Early involvement of a multidisciplinary team with aggressive elevation, splinting, hand therapy, and early excision and grafting for deep burns is essential.
- Hand burns that are unlikely to heal within 2 weeks of injury should undergo tangential excision and skin grafting.⁵
- Palmar burns are more likely than dorsal burns to heal spontaneously from glabrous skin appendages and may be less likely to require grafting.
- Approximately 78% of pediatric palm burns heal without the need for grafting; however, flexion contractures of the fingers and/or shortening of the thenar-hypothenar distance may occur when burns take greater than 2 to 3 weeks to heal.^{6,7}
- Secondary burn deformities may occur as a child grows because burn scars do not grow at the same rate as the rest of the child's hand and may impede overall bone and soft tissue growth.³
- Secondary burn deformities include intrinsic minus deformities ("claw hand"); palmar cupping deformity; web space deformities; hypertrophic scars and/or scar bands; finger deformities including boutonniere, swan neck and mallet deformities; and deformities of the nail.⁸

PATIENT HISTORY AND PHYSICAL FINDINGS

- Evaluation of the location, size, depth, and previous treatment of the burn
- Mechanism of injury (thermal, contact, chemical, electrical)
- Previous splinting and hand therapy
- Nature of the contracture (extension, flexion)
- Skin and soft tissue adequacy and contracture
- Tendon function—flexor and extensor
- Assessment of sensation and vascular status of the hand and digits

- Joint contractures—passive and active range of motion
- Bony deformities and inadequate growth
- Assessment of the entire upper extremity
 - Wrist or elbow contractures may need to be addressed to adequately position the hand in space.

IMAGING AND DIAGNOSTIC TESTS

- Plain radiographs of the hands and digits should be assessed for bony deformities, joint contractures, or destruction.

SURGICAL MANAGEMENT

- Surgical intervention is warranted for functionally significant contractures not improving with stretching and splinting.³
- Multiple surgeries may be required as a child grows for recurrent contractures.
- Thumb reconstruction
 - The thumb contributes up to 50% of function of the hand, and secondary reconstruction is critical in restoration of hand function.
 - When thumb loss remains distal to the interphalangeal joint, function is reasonably well preserved.⁹
 - Web space deepening in these cases can help maximize function with techniques such as the 4 or 5 flap Z-plasty and release with full-thickness skin graft (FTSG) as described above.
 - As the thumb loss extends proximal to the interphalangeal joint, function becomes increasingly more impaired.
 - Procedures to lengthen the thumb in these cases include pollicization of the index finger, osteoplastic reconstruction, distraction lengthening, and toe-to-thumb transfer.
 - Soft tissue is frequently limited and groin flaps or free tissue transfers are often necessary as a first stage to provide a sufficient soft tissue envelope for the transplanted toe.⁹

Preoperative Planning

- An operative plan should be developed based upon the structures affected: skin, tendon, joint, and bony structures should be addressed based upon their involvement in the contracture.
- Advanced joint destruction may warrant arthroplasty or arthrodesis.
- Hand mobility, strength, and sensation are important to overall function and

should be carefully assessed in conjunction with an experienced hand therapist.

- It is important to consider how the burn has previously been treated and if previous surgery has been performed, as it may change the operative approach.

Positioning

- The patient is positioned supine on the operating table. A hand board is attached to the table and centered on the patient's axilla. The affected extremity is then extended with the hand positioned either dorsal or volar on the table.
- A malleable lead hand may be used to secure the hand and fingers.
- A nonsterile tourniquet may be used on the upper arm.

TECHNIQUES

■ Z-Plasty (Standard, 4- or 5-Flap, Multiple Z-Plasties in Series) for Thumb Reconstruction

- Z-plasties are used to break up a tight linear scar when there is unscarred soft tissue that can be transposed and is particularly useful for the web spaces of the hand (**TECH FIG 1A**).⁹
- In circumstances where flaps to be transposed are significantly scarred, consider an alternative procedure such as release and grafting.

TECH FIG 1 • A. Scar band across axilla. **B.** Z-plasty in series. **C.** Final appearance of Z-plasty in series following closure.

- 4-Flap or 5-flap “jumping man” Z-plasties are typically used for web space contracture release and are designed with the transverse limb parallel to the web space and all limbs being equal in length.
- With the 4-flap Z-plasty, 90-degree flaps are drawn at the end of each central limb and bisected to give 45-degree flaps.
- Multiple Z-plasties in series should be used to break up a long vertical scar band (**TECH FIG 1B,C**).
- Incisions are made down through subcutaneous tissue and flaps are elevated as thick as possible, allowing for preservation of blood supply (**TECH FIG 2A**).
- Flaps should be dissected until they transpose easily without any tension

(**TECH FIG 2B,C**).

- In the 1st web space, care should be taken in the dissection to avoid injury to the index radial neurovascular bundle, which lies beneath the flap.
- The tourniquet should be released and flaps checked for viability. Hemostasis should be achieved with pressure and cautery.
- Flaps should be transposed into position and secured with 4-0 or 5-0 suture (**TECH FIG 2D**).

TECH FIG 2 • **A.** Flaps elevated. **B,C.** Transposition of flaps. **D.** Closure.

■ **Contracture Release With Full-Thickness Skin Grafting**

- Indicated for flexion contractures of the digits, contractures of the dorsal or volar of the hand, and web space contractures or syndactylies

Incision and Release

- Scar contracture is assessed for area of maximal tightness and transverse incision marked at this location (**TECH FIG 3A,B**).
- Incision must extend into unscarred tissue on either side of the contracture band to provide complete release (**TECH FIG 3C**).
- Release is performed by pushing into the scar contracture with the blade while counter tension is applied to the digit by stretching it into extension. The tight thick scar will give way in the release using pushing movement with a fresh blade, whereas the underlying neurovascular bundle will be unharmed, under the appropriate pushing tension.
- Continue to use pushing technique against scar until complete release is achieved.
- Identify underlying flexor tendons and neurovascular bundles and avoid injury.
- Slow passive stretch on a digit can help further stretch soft tissue.
- Following soft tissue release, the contracture is reassessed to determine if any release of checkrein, collateral ligaments, or volar plate is required.
- The tourniquet is released and digits assessed for capillary refill and color. If the digit appears pale with slow capillary refill, it may not tolerate the extent of the contracture release due to the stretch on the neurovascular bundles. In this case, the digit should be extended only to the point where it retains normal color and capillary refill.
- Meticulous hemostasis of the defect site is achieved.
- If there is significant memory of the digit following contracture release, a K-wire can be placed across the joint to maintain its position in extension (**TECH FIG 3D**).
- Color and capillary refill should be checked again after K-wire placement to ensure the digit can tolerate the extended position.

TECH FIG 3 • A,B. Dorsal hand burn. **C.** Following release. **D.** Following release and pinning of MCPs.

Graft Placement

- The defect from the soft tissue release outlined using a template from suture packet or Esmarch bandage.
- The template is transposed to desired site of full-thickness skin graft (FTSG) harvest (upper arm if available) and outlined in ellipse.
- FTSG is harvested and defatted. Donor site is closed in layers.
- FTSG is secured at the defect site with 5-0 chromic or plain gut suture.
- A thick split-thickness graft may also be used (**TECH FIG 4A**).
- Saline irrigation with a syringe and catheter tip beneath the graft to flush any clots is performed.
- A compression dressing with wet cotton and gauze is applied to the graft site, followed by a splint to maximally protect position of release and graft (**TECH FIG 4B**).

TECH FIG 4 • A. Resurfaced with thick split graft. **B.** Dressed with dorsal block splint.

PEARLS AND PITFALLS

Neurovascular limitations

- It is critical to recognize signs of digital neurovascular compromise intraoperatively and ensure the digit is returned to a position where the neurovascular structures are under less tension, in particular with the PIP joint release when the neurovascular structure may be under tension with full stretching of the joint after release.

Incomplete contracture release

- Soft tissue contractures must be completely released and joint and ligamentous structures examined in sequence if the contracture remains.

Immobilization of the graft site

- An inadequate compression dressing or failure of extremity immobilization may result in suboptimal skin graft take.

Therapy

- Postoperative splinting is critical to preventing recurrence of contractures.

POSTOPERATIVE CARE

- To avoid any mobility at the graft site, a cast is applied (long arm in young child).
- Healing and graft take is assessed at 7 to 10 days, and daily dressings are performed if healing is incomplete.
- If a K-wire is present, it is removed at 4 to 6 weeks. The patient should remain

in a cast to protect the K-wire for the duration.

- Activities may be resumed once grafts are completely healed and K-wires removed.
- Night splinting in maximal extension to prevent recurrence of the deformity should continue for 3 to 6 months.

COMPLICATIONS

- Infection
- Wound healing problems
- Limited mobility from recurrent contractures
- Hypertrophic or keloid scarring
- Pain

25 Reconstruction of Burned Eyelids

CHAPTER

David A. Billmire and Kim A. Bjorklund

DEFINITION

- The majority of ocular sequelae following facial burns occur as a result of secondary eyelid deformities.¹
- Burn scar contracture can lead to cicatricial ectropion and lagophthalmos, which may in turn produce exposure keratopathy and in severe cases result in corneal scarring.

ANATOMY

- The eyelids are complex structures providing protection and lubrication for the surface of the globe.
- They contain an anterior and posterior lamella, which are separated by the orbital septum.
- In children, the levator muscle is rarely involved.
- Eyelid skin is naturally thin and may result in a deeper burn than a similar heat exposure elsewhere in the body.
- Contractures most often affect the lower lids.
- Reduction of motion and coverage may be the result of direct scar contracture to the lid itself (intrinsic) or burn scar contracture in sites remote to the lids such as the cheeks, mouth, neck, and forehead.

PATHOGENESIS

- Burn scar contracture affects the motion and excursion of the lids and consequently the coverage of the cornea.
- With deeper burns, lagophthalmos of the lids develops and places the eye at risk.

- Bell phenomenon reflex helps prevent corneal epithelial defects and may be problematic if absent such as in heavily sedated or paralyzed patients.¹

NATURAL HISTORY AND PHYSICAL FINDINGS

- Patients frequently present with an inability to fully close their eyes and may complain of irritation and discomfort.
- The eyes should be carefully examined to determine the etiology of the dysfunction, noting if the anterior or posterior lamellae are affected and whether there are additional extrinsic burn scars contributing to the contracture.
- These symptoms tend to be better tolerated in children than adults.
- The depth and extent of the eyelid burns should be noted, as well as presence of eyebrows and eyelashes.¹
- The eyelids tend to demonstrate stiffness and fail to completely cover the eyes, which may be most noticeable when the patient is asleep. Parents should be queried about the status of the lids when the child sleeps. It is also easily noticed when the child is under anesthesia.
- The conjunctiva of the lower lids may be everted and pulled down onto the cheeks.
- The upper lids may demonstrate “clotheslining” where a band of scar runs from the lateral canthus to medial canthus and functions as a fixed point holding the lid up and preventing closure.
- Reconstructive planning should include examination of both upper and lower eyelids, extent of surrounding scar, including cheek and forehead, and donor sites for potential FTSG.

NONOPERATIVE MANAGEMENT

- In mild to moderate cases, eye drops and lubricants and taping can be used temporarily until definitive release is performed.
- In the acute burn phase, corneal exposure may be managed by a temporary tarsorrhaphy, which is replaced as soon as the patient is stable with a formal eyelid release-resurfacing.
- The eyelids are delicate structures and tarsorrhaphies routinely pull out and fail and should not be relied upon for an extended period of time.

SURGICAL MANAGEMENT

- Operative intervention to protect the cornea and counteract lid retraction should be considered a priority in burn reconstruction.

- The timing of surgery is dictated by evidence of lagophthalmos with signs and symptoms of corneal exposure.¹
- If both lids will require release, it is best to stage them by addressing the more involved lid first for appropriate overcorrection.
- Lower lid
 - Both extrinsic and intrinsic sites of the contracture should be released, but even in a minimally involved lower lid attention should first be directed to the lid itself.
 - As with all burn scar contractures, it should be overcorrected.
 - Although an extrinsic contracture with an unaffected lower lid may be released, often the lower lid will still not achieve a normal position. In these cases, the lower lid will need to be released and overcorrected, even though there is no scar.
- Upper lid
 - The surgical approach is similar to the lower lid.
 - Again the levator muscle is rarely involved and when involved actually results in ptosis. This could be the result of dehiscence or destruction.
 - The lid should be resurfaced and released prior to addressing the ptosis.
 - Depending on the state of the levator, it can be repaired or a suspension technique utilized.

Preoperative Planning

- Review photographs and carefully examine the patient to determine etiology of the problem.
- Choose an appropriate donor site, preferably glabrous and thin. Acceptable sites are an unburned opposite lid, retroauricular or preauricular, supraclavicular, or the inner upper arm for full-thickness skin grafts.

Positioning

- Supine, with shoulders elevated by a shoulder roll.
- Ensure the donor site is accessible.

TECHNIQUES

■ Lower Lid Reconstruction

- The approach is the similar to a blepharoplasty approach for both the upper and lower lids.
- Local anesthetic with epinephrine should be injected.
- In the lower lid, a subciliary incision is performed with a 15 blade and dissected down to the orbicularis oculi muscle.
- The incision should be continued from canthus to canthus, extending beyond the medial and lateral canthi to ensure a complete release.¹
- Hooks or a Frost suture is used to apply steady traction to the lid margin pulling superiorly as you release the scar.
- The release should continue until the lid margin easily approximates the globe.
- Orbicularis muscle may require dissection if scarred, but typically, the orbital septum is not involved and should not be violated.
- A lateral canthotomy and cantholysis with subsequent canthoplasty may need to be performed.

■ Upper Lid Reconstruction

- Approach is similar to a blepharoplasty with an incision along the likely tarsal crease, approximately 1 cm along the lash line (**TECH FIG 1A**).
- The incision should be extended more medially and laterally than in a standard blepharoplasty (**TECH FIG 1B**).
- Apply gentle traction and continue to divide the scar until the lid comes down.
- As with the lower lid, the release should be overcorrected.
- Do not violate the orbital septum.
- The conjunctival surface should easily redrape over the globe.
- A pattern of the defect is made and transferred to the donor site (**TECH FIG 1C**).
- Harvest a full-thickness graft and defat as necessary.
- In extensive burn cases, a split-thickness graft may be necessary.
- Sew the graft in place with an absorbable suture, such as 6-0 chromic.
- A bolster should be applied such as a thin Reston foam tailored stent over a nonadherent gauze (Adaptic) impregnated with an ophthalmic ointment. The

bolster should be sewn in place again with an absorbable suture and left for 7 to 10 days (**TECH FIG 1D**).

- A tarsorrhaphy is unnecessary with this technique as the bolster holds the eyelid in position and allows the child to have some vision in the affected eye.
- Using this method, release and reconstruction of both eyes may be performed at the same time.

TECH FIG 1 • **A.** Planned incision. **B.** Lid released with medial and lateral extensions. **C.** Post auricular donor site. **D.** Graft placed and stented.

Ophthalmol. 2009;54(3):356-371.

26 Burn Neck Contracture Release

CHAPTER

David A. Billmire and Kim A. Bjorklund

DEFINITION

- Burn scar contractures of the neck are relatively common and should be a priority in surgical reconstruction when indicated.
- Burn contractures of the neck may result in deformities that impair functions such as eating and speaking.
- If severe, the contracture can compromise the airway, make intubation difficult, and distort growth of the facial skeleton.¹

ANATOMY

- Anterior neck contractures have been classified based upon the location of the band and the degree of flexion and extension away from the anatomical position of the neck and jaw.²
- The width of the contracting segments and availability of supple surrounding skin is also considered in the classification of the deformity.²
- The key anatomical considerations are the burn scar crossing the mobile cervical-mental angle or the manubrium.
- Burn scarring above the cervical-mental angle will primarily affect the chin, lower lip, and mandible.
- When the burn crosses the angle, the mandible and head are pulled into flexion.

PATHOGENESIS

- Neck burn scar contractures in the pediatric patient can be severe secondary to the propensity to hypertrophic scarring, which may develop rapidly in the initial weeks following the injury.

- Significant neck burn scarring creates a persistent downward force on the lower lip, chin, and eyelids resulting in ectropion and AP growth restriction of the mandible.³
- Contractures may be severely disfiguring and functionally impair neck motion, making eating and communication problematic.
- The airway may become compromised and intubation difficult.
- In extreme cases, scarring pulls the chin down to the chest wall, elongating the mandible and severely affecting the airway.

NATURAL HISTORY

- The natural history and progression is dependent on the depth of the burn wound, the inherent tendency toward scarring, the age of the child, and the initial treatment and management.
- Neck burn scar can exert considerable pressure on the growing mandible and adversely affect growth.
- Depending on the vector of pull, the AP growth of the mandible can be negatively affected and require later genioplasty or even a BSSO with advancement.¹
- In the most severe cases where the mandible is drawn down to the chest, mandibular lengthening and eventual setback may be required.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed assessment of the patient's functional limitations is documented.
- Previous treatment of the neck burn injury should be noted as well as compliance with stretching and splinting.
- Note the specific anatomic location of the neck burn contracture, width of scar bands, and whether supple nonburned soft tissue is present.
- Deformities such as lower lip and eyelid ectropion affected by the neck contracture should be noted.
- Occlusion is assessed—loss of chin projection and class II occlusion may develop over time.
- Range of motion and ability to extend the head and neck should be measured.
- The patient should be assessed for potential intubation difficulty.
- Availability of potential donor sites for surgical planning should be assessed.

IMAGING

- Imaging is rarely required unless growth disturbances are suspected.

- A standard lateral cephalogram is useful to follow the patient.

NONOPERATIVE MANAGEMENT

- In the scar maturation phase of the burn wound, splinting and stretching are recommended to reduce the contracture.

SURGICAL MANAGEMENT

- Depending on the severity and extent, contracture releases may be accomplished by a variety of techniques including split-thickness or full-thickness skin grafting, local flaps, tissue expansion, and local flaps or a free flap.
- Operative intervention is warranted for functional deformities that are not amenable to stretching and splinting.
- The majority of neck contractures can be managed with a thick split-thickness skin graft and may also be staged by initial release with a skin graft to assure a safe airway and at a later date resurfaced with tissue expansion or flap.
- In a growing child, releases may need to be repeated.
- Recurrence is also significantly affected by the use of long-term postoperative splinting:
 - In a study of 143 neck release procedures with Z-plasties or STSG, the postoperative use of a neck hyperextension brace for over 1 year following skin grafting decreased the recurrence rate by 40% to 50%.⁴

Preoperative Planning

- Consultation preoperatively with anesthesia is critical for any potential for a compromised airway and difficult intubation.
- Although fiberoptic intubation has facilitated the process, in severe cases, it is appropriate that the surgeon be at the bedside to do an emergent release if the anesthesiologist is unable to establish a safe airway.

Positioning

- The patient is positioned supine on the operating table.
- A transverse shoulder roll is placed to allow maximum extension of the neck.

TECHNIQUES

■ Incision and Release

- Local anesthesia with epinephrine may be injected to help with hemostasis and developing a dissection plane.
- The neck is typically incised along the cervicomenal angle and extends from mid axis to mid axis or further if necessary to obtain complete release (**TECH FIG 1A,B**).
- The incision is carried down to a scar-free plane, which usually includes division of the platysma with the lateral extension into the unburned skin on either end.
- The wound is then spread using digital traction or retractors to achieve release of the scar.
- This is aided by extending the neck as much as possible and using continuous slow traction to release the contracture as much as possible.
- It is important to overcorrect the contracture release as there will be subsequent secondary contracture with healing.
- Care should be taken to avoid injury to neurovascular structures deep to platysma.

TECH FIG 1 • Incision for neck flexion contracture release, anterior view (**A**) and lateral view (**B**). **C**. Appearance of neck following release and grafting.

■ Reconstruction

- When the wound is spread to its fullest extent, meticulous hemostasis is achieved.
- A thick split-thickness graft (14 to 16 thousands of an inch) sheet graft is harvested, pie crusted, and sewn into place (**TECH FIG 1C**).
- The graft is then stabilized with a tailored Reston foam stent sewn over a nonadherent gauze (Adaptic) coated with Bacitracin ointment.
- Alternatives to Reston foam include a bolster dressing.
- In difficult recurrent cases, it may be necessary to consider the use of a flap as opposed to a graft. Options include trapezius fascial or myocutaneous flaps,⁵ supraclavicular flaps,^{6,7} or a free flap of choice.
- Integra dermal substitute has also been described as a reconstructive option.⁸

PEARLS AND PITFALLS

Contractures	■ Burn contractures of the neck require early treatment to prevent compromise of the airway and impairment of functions such as eating, speaking, and growth of the facial skeleton. ■ Anatomically, it is critical to note burn scars crossing the cervical-mental angle, which result in a flexion deformity as the mandible is drawn to the chest.
Airway	■ Preoperative anesthesia assessment is critical for potential compromised airway and difficult intubation.
Surgical technique	■ Ensure complete contracture release in plane deep to platysma with incision along the cervical-mental angle.
Postoperative splinting	■ Postoperative management with neck splinting to prevent recurrence of the contracture until the scar is fully mature is essential.

POSTOPERATIVE CARE

- The foam bolster is left in place for 10 to 14 days.
- Following removal, a neck brace is crafted to hold the neck in an extended position.
- It will be worn ideally 24 hours a day until the scar matures and may be beneficial for up to a year.

- For small releases one can also consider a soft collar.

OUTCOMES

- Despite a successful release, it may have to be repeated due to subsequent contracture secondary to growth in children.
- Factors include the age of the patient, the degree of scar response and the adherence to the postoperative regimen.⁹
- Failure due to significant hypertrophic scarring may require the use of a flap; however, even flaps can fail as surrounding scar may create tension and result in vascular compromise to the flap.
- Once a stable neck release is obtained, it is often possible to replace the grafted area at a later date by using tissue expansion to expand the unburned skin on the lateral neck and supraclavicular area if available.

COMPLICATIONS

- The major complications are graft loss and recurrence of the contracture.

27 Adolescent Burned Breast Reconstruction

CHAPTER

David A. Billmire and Kim A. Bjorklund

DEFINITION

- Burned breast contractures and loss are a common occurrence in females who sustain major burns injuries prior to adolescence.
- Knowledge of the importance of preserving the breast bud in preadolescent females has lessened the need for complete reconstruction.^{1,4}
- In the acute burn phase, debridement should be kept to a minimum in the area of the nipple areolar area.²

PATHOGENESIS

- With the onset of puberty, the breast bud will begin to grow and expand the overlying skin acting much like a tissue expander.⁴
- Any overlying scar can cause restriction and/or distortion of the maturing breast mound.
- Additionally, full-thickness tissue loss from the burn injury surrounding the breast bud will cause additional loss in the eventual volume of the breast.
- Complete loss of the breast bud itself will result in a smaller or absent breast.
- Burn wounds may also result in the loss of the nipple areolar complex, despite the development of an acceptable breast mound.

NATURAL HISTORY

- Full-thickness and deep second-degree burn injuries to the female chest warrant special care in the acute burn wound and careful management in the subsequent time period prior to development of the breast.³⁻⁵
- Care should be taken with axillary releases, especially when considering the use of Z-plasties. An inappropriately designed Z-plasty can unknowingly

transpose the breast bud into the axilla.

- As the breast develops, the amount of constriction and distortion will become apparent.
- It is advisable to delay release/reconstruction until the breast has reached its full size.
- Rarely, the release may be warranted prior to growth completion and will most likely need to be repeated.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Long-term follow-up for young females with significant chest burns is critical to identify any problems during adolescence.⁴
- Once the breast has begun developing, the patient should be evaluated about every 6 months to assess potential problems.
- The soft tissue envelope of the breast, breast tissue, and nipple areolar complex should be assessed, noting location and degree of scar contracture.
- Age and stage of breast development should be determined at each visit.
- Restriction can be complicated by inherent underlying congenital deformations such as constricted breast, tubular breast deformity, or Poland syndrome. These should be considered in addition to the burn injury deformity.

SURGICAL MANAGEMENT

Preoperative planning

- All areas of constriction and distortion should be noted.
- Breasts are treated with almost entire release and grafting and/or resurfacing.^{4,5}
- Typical areas of release are the inframammary, intermammary, and the periareolar sites.
- Reconstruction is typically performed with split-thickness sheet grafts, although dermal templates such as Integra have been described.⁶

Positioning

- The patient is placed supine on the operating table with a shoulder roll and the arms abducted at 60 degrees.
- Graft donor site should be exposed, typically the thighs or legs. The back is also a good choice but requires turning the patient.

Approach

- Both inframammary and intermammary releases are frequently performed at the same time.
- The inframammary release should be at the level of the inframammary fold (which is frequently obliterated by burn scar) and will curve up at the midline, joining the incision from the opposite side (**FIG 1**).

FIG 1 • Incision design for breast release along inframammary fold.

TECHNIQUES

- The incision is made as indicated.
- The underlying breast mound is pulled superiorly to open the release and define the inframammary fold.
- At the midline, the breasts are retracted laterally to separate the breasts into

two distinct mounds and define the cleavage (**TECH FIG 1**).

- A periareolar release may be performed following the curve of the areolar, although it may be delayed to a second operation if necessary.
- Sheet grafts (approximately 15/1000ths thick) are harvested with a dermatome from the chosen donor site.
- Grafts are sewn in place and tacking sutures are placed along the inframammary crease. The graft may be piecrusted to allow escape of underlying fluid.
- The grafts are dressed with nonadherent gauze and antibiotic ointment. Moist fluffed gauze is molded along the inframammary fold followed by a tailored Reston foam bolus, which can be sewn or stapled into place.

TECH FIG 1 • Appearance of breasts following release and grafting—inframammary and intermammary definition apparent, anterior view (**A**) and lateral view (**B**).

PEARLS AND PITFALLS

Burned

breast deformity

- In the burned breast with inherent congenital deformities (such as constricted or tuberous breast), release and correct the burn deformity first and approach the congenital deformity secondarily.
- Address the nipple areolar deformity at a later date once scars have matured and edema has settled.
- Volume loss can be treated with fat grafting at a later date.

Loss of the breast

- Complete loss of the breast can be approached by any of the techniques used in breast cancer reconstruction ranging from tissue expansion,⁷ pedicled flaps such as latissimus dorsi⁸ or TRAM flaps, to free tissue transfer.
- The reconstruction should consider the state of the breast site, the quality of the tissue, and available donor sites.
- Nipple areolar reconstruction likewise can be addressed by the standard techniques used for breast cancer patients.
- Contralateral breast procedures to address asymmetry may be required if only one breast is affected.

POSTOPERATIVE CARE

- Bed rest is not required, and early ambulation should be encouraged.
- The dressings are left on for 10 to 14 days.
- After the initial dressings are removed, the patient is dressed in a light padded gauze dressing and a longline or surgical bra until the grafts are stable.
- The patient is then switched to silicone inserts molded for the inframammary fold to apply pressure the maturing graft.

28 Pressure Injuries (Sacral and Pelvic Region, Columella—From CPAP)

CHAPTER

David A. Billmire and Kim A. Bjorklund

DEFINITION

- A pressure injury is a localized injury of skin and underlying tissue secondary to prolonged pressure, frequently in combination with shear forces.
- Severity ranges from nonblanchable erythema to full-thickness tissue loss.
- Common locations are over bony prominences such as the sacrum, coccyx, ischium, and heels.
- In the pediatric population, children with special needs and those who are critically ill are at particularly high risk for pressure injuries.¹

PATHOGENESIS

- Pressure injury formation is a complex process that involves numerous factors.²
 - Extrinsic contributing factors include pressure, friction, and shear.
 - Intrinsic factors include local tissue ischemia, decreased autonomic control, infection, loss of sensation, decreased mental status, fecal or urinary incontinence, anemia, and hypoproteinemia.^{3,4}
- As muscle is more sensitive to pressure than is skin, areas with a significant amount of muscle may be susceptible to an inverted cone pattern of injury, in which most of the necrosis is deep to the skin.⁵
- Particular risk factors in the pediatric population have been identified^{1,6}:
 - Paraplegia, sensory impairment
 - Cognitive impairment
 - Kyphoscoliosis or kyphosis

- Chronic fecal or urinary soiling
- Trauma
- Immobility
- Poor nutrition

NATURAL HISTORY⁷

- Nonblanchable erythema may be observed within 30 minutes of unrelieved pressure and typically disappears within 1 hour after pressure is eliminated.
- Ischemia develops after pressure is present for 2 to 6 hours.
- Necrosis may occur if pressure is not relieved within 6 hours.
- Ulceration tends to occur over bony prominences within 2 weeks after development of necrosis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Determine factors contributing to the pressure injury (extrinsic and intrinsic) and whether they can be eliminated postoperatively.
 - Note any chronic medical conditions contributing to the pressure injury, such as myelodysplasia, cerebral palsy, paraplegia, and scoliosis.
 - Note any temporary conditions contributing to the pressure injury (prolonged immobility, repetitive trauma) that require resolution.
- Ambulatory status
- Previous pressure injuries
- Compliance and motivation with treatment
- Assess risk factors using Braden Scale, including mobility, activity, sensation, moisture, friction/shear, and nutrition.
- Assess sensation and lower extremity motor function, including spasticity.
- Palpate for any fluctuance or bony prominences.
- Note any signs of infection such as warmth, erythema, tenderness, purulent drainage, and systemic signs of infection.
- Assess ongoing factors that may be contributing to wound breakdown, such as items causing pressure, spasticity, and fecal or urinary incontinence.
- Staging of pressure injuries based on the updated guidelines of National Pressure Ulcer Advisory Panel⁸:
 - Stage 1: Nonblanchable erythema of intact skin
 - Stage 2: Partial-thickness skin loss with exposed dermis
 - Stage 3: Full-thickness skin loss

- Stage 4: Full-thickness skin and tissue loss
- Unstageable pressure injury: Obscured full-thickness skin and tissue loss
- Deep tissue pressure injury: Persistent nonblanchable deep red, maroon, or purple discoloration

IMAGING AND DIAGNOSTIC STUDIES

- Nutritional assessment (including albumin, prealbumin, electrolytes)
- Wound cultures if concern for infection
- WBC and ESR if concern for infection/osteomyelitis
- MRI or CT scan may help in identification of osteomyelitis and communicating sinus tracts.
- Bone biopsy and culture if concern for osteomyelitis prior to treatment with antibiotics

NONOPERATIVE MANAGEMENT

- Generally indicated for stage 1 and 2 pressure injuries
- Correct nutritional deficiencies and medical comorbidities.
- Control spasticity.
- Treat infection with local wound care and culture-directed antibiotics.
- Cleaning, debridement (mechanical, autolytic, enzymatic, sharp), and local wound care of pressure injuries
- Local wound care should be adjusted based on the nature of the wound (exudative, granulating, fibrinous).
- Pressure relief through frequent repositioning and protective padding; support surfaces that minimize pressure and reduce shear.
- Prevent contamination from urinary and fecal soiling.
- Routine inspection by caregivers for early pressure changes and timely referrals during growth spurts for assessment of orthotics, prosthetics, or wheelchairs are critical.

SURGICAL MANAGEMENT

- Surgery is indicated for large stage 3 or 4 pressure injuries that require debridement and reconstruction.
 - Goals include preventing osteomyelitis and protein loss through the wound; improving function, hygiene, and quality of life; and reducing rehabilitation and wound care costs.⁸
- Ischial pressure injuries: Common reconstruction options include gluteal

muscle rotation flaps, posterior thigh V-Y advancement flap (hamstring muscles may be included if nonambulatory), or gracilis musculocutaneous flap.

- Sacral pressure injuries: Common reconstruction includes bilateral V-to-Y gluteus advancement, gluteus maximus myocutaneous flap, and superior gluteal artery perforator flap.⁸
- Coccygeal pressure injuries can be treated with coccygectomy.
- Trochanteric pressure injuries are typically reconstructed with tensor fascia lata flap.

Preoperative Planning

- Identify and address causes of the pressure injury.
- Control comorbidities.
- Optimize nutritional status, including serum albumin and hemoglobin.
- Consider diverting colostomy and catheterization to minimize urinary and fecal soiling.
- Careful consideration of future pressure sores in planning of operative technique

Positioning

- The patient is positioned prone on the operating table with pressure points well padded.
- General anesthesia is administered.

TECHNIQUES

■ Debridement

- Completely excise injured area, bursa, scar, and all necrotic tissue.
- Debride all nonviable bone and calcifications.
- Bony debridement should continue until healthy bleeding bone is apparent.
- Biopsy of underlying bone should be sent for culture and pathology.
- Reconstruct by filling dead space with well-vascularized muscle or fascial flaps inset without tension.
- Pressure injury recurrence or formation in new locations should be carefully considered in reconstructive planning.

- Drains should be placed under the flap.

■ V-Y Advancement Flap for Ischial Pressure Injuries

- V-Y biceps femoris musculocutaneous advancement flap design for ischial pressure injury (**TECH FIG 1A**).
- Reconstructed ischial pressure injury with V-Y biceps femoris flap (**TECH FIG 1B**).

TECH FIG 1 • A. V-Y biceps femoris musculocutaneous advancement flap design for ischial pressure injury. **B.** Reconstructed ischial pressure injury with V-Y biceps femoris flap.

■ Gluteus Maximus Myocutaneous Flap

- Unstageable right ischial pressure injury prior to debridement (**TECH FIG 2A**)
- Following debridement, a gluteal rotation flap design is outlined (**TECH FIG 2B**).
- The defect from the pressure injury is triangulated with the apex toward the flap pedicle.
- Rotation flap is outlined approximately 5 times the length of the defect base.
- Gluteal skin and muscle are incised, and the flap is elevated until it can be mobilized into the defect (**TECH FIG 2C**).
- A small back cut can be performed at the end of the rotation flap.
- Flap should be closed in layers over suction drains (**TECH FIG 2D**).

TECH FIG 2 • A. Ischial defect following debridement with gluteal rotation flap design outlined. **B.** Gluteal skin and muscle are incised and the flap elevated until it can be mobilized into the defect. **C.** Flap should be closed in layers over suction drains.

■ Bilateral V-to-Y Advancement of Gluteal Muscles

- Following debridement of sacral pressure injury, bilateral V-Y gluteal flaps are marked extending from the edges of the debrided pressure injury at the sacrum medially and including the entire gluteal region (**TECH FIG 3A**).
- Skin incisions are performed, and the gluteus maximus muscle is identified.
- It is detached from sacral attachments medially and iliac crest attachments superiorly.
- Superior and inferior gluteal vessels must be preserved.
- The lateral and inferior aspects of the myocutaneous flap are incised and elevated at the edges to allow for advancement.
- Gluteus myocutaneous flaps are then advanced to the midline.
- Closure is performed in a V-to-Y fashion (**TECH FIG 3B**).
- Suction drains are placed under each flap.
- Large absorbable sutures such as 2-0 Vicryl or PDS should be used for deep tissue approximation.
- Deep dermal and subcuticular layers should then be closed.

TECH FIG 3 • A. Bilateral V-Y gluteal myocutaneous flaps extend from the edges of the sacral pressure injury at the sacrum medially and include the entire gluteal region. **B.** Closure is performed in a V-to-Y fashion.

PEARLS AND PITFALLS

General

- Ensure the underlying etiology of the pressure injury is corrected prior to surgical reconstruction.
- Comorbidities, nutritional deficiencies, fecal/urinary contamination, infection/osteomyelitis, and postoperative pressure relief plan must be addressed prior to reconstruction.
- Plan flap reconstruction accounting for possible recurrence of the pressure injury and new pressure injury.

Debridement

- Adequate debridement for the pressure injury is critical to a successful outcome.

Ischial, sacral, trochanteric pressure injuries

- Complete excision of the bursa as well as any nonviable tissue is essential.
- Failure to adequately debride bone or bursa may lead to failure of the reconstruction.
- Consider staging the reconstruction if there are uncertainties regarding infection or tissue/bone viability.
- Ambulatory status of the patient must be determined if considering use of gluteal or hamstring muscles in flap reconstruction.
- Gluteal rotation, posterior thigh, and TFL flaps must be designed with adequate dimensions to fill the defect.
- Ensure the vascular pedicle is preserved in design and dissection of flap.
- Ensure the flap is not inset under tension.
- Do not excise dog ears or extra tissue.
- Always close flaps over a drain.

POSTOPERATIVE CARE

- Patients should be non–weight bearing on the operative site for up to 6 weeks postoperatively.
- Prone or lateral decubitus positioning should be maintained to avoid pressure on the site.
- Pressure relief adjuncts such as low air loss beds should be used to prevent development of additional pressure injuries.
- Nutrition status should be closely monitored in the postoperative period to promote good wound healing.
- After wounds are healed, sitting protocols should be used to gradually increase the amount of time spent sitting.
- Pressure relief should be performed every 15 minutes when in the seated position.⁹

OUTCOMES

- Pressure injuries represent a major burden of illness, affecting the quality of life of patients and their families.¹⁰
- For patients at high risk for pressure injuries, it is critical that pressure relief measures—such as specialized support surfaces, frequent repositioning, and efforts to minimize shear, moisture, and spasticity—are adhered to.
- Optimizing nutrition and limiting medical comorbidities are also essential in

avoiding a high likelihood of recurrence.

- High-risk patients should be followed regularly by a physiatrist for evaluation and care.
- Education on prevention and treatment of pressure injuries is critical to successful outcomes.

COMPLICATIONS

- Hematoma
- Seroma—important to maintain suction drain beneath reconstruction until minimal output
- Wound dehiscence—if small, may heal with local wound care and offloading pressure
- Wound infection
- Recurrence is high if patients who are noncompliant or do not have medical management optimized preoperatively are at high risk of postoperative recurrence.

CHAPTER Pressure Injuries

Lawrence J. Gottlieb and Maureen Beederman

DEFINITION

- A pressure injury is a soft tissue injury due to the complex interplay of tissue deformation, stress, strain and ischemia from unrelieved pressure, shear, and friction typically overlying bony prominence.¹
- The standard for classifying pressure injuries is based on the four grades originally described by Shea in 1975.²
- Grades I and II have potentially reversible acute inflammatory reactions involving all soft tissue layers; grade III has full-thickness tissue loss, extending to fascia; and grade IV extends through the deep fascia to bone.
- Skin loss in grades I and II is thought to be more likely due to shear, friction, and maceration rather than pressure per se.
- Over time, refinements have been made to this classification with the most recent being a six-stage classification by The National Pressure Ulcer Advisory Panel during their 2016 Staging Consensus Conference.³

ANATOMY

- Pressure injuries typically occur over bony prominences and are dependent on patient positioning.
 - Supine: greatest pressure overlying heels, sacrum, occiput, and scapula
 - Sitting: greatest pressure at ischial tuberosities, elbows
 - Lateral decubitus: greatest pressure over greater trochanters (often accompanied by hip flexion contractures), fibular head, and malleoli
- Pressure injuries also occur due to inadvertent pressure from external objects pressing on the skin (ie, IV connectors, side rail of bed pressing on the skin or small object in shoe of the patient with neuropathy) or securing devices too

tight (ie, nasal tubes, CPAP devices).

- Extrusion of internal objects (ie, hardware or internal prosthetic or tubing) is generally caused by the same pathophysiology of classic pressure injuries over bony prominences.

PATHOGENESIS

- Unrelieved pressure
 - External pressure greater than capillary pressure leads to decreased blood flow and tissue ischemia, eventually causing tissue necrosis.
 - Pounds-per-square-inch pressure highest in thin patients over bony prominences. Obese patients are able to distribute pressure better.⁴
- Reperfusion injury
 - Tissue loss after restoration of blood flow and generation of oxygen free radicals after relief of pressure
- Deformation injury of cells
 - Local cell damage and death
- Tissue breakdown may also occur due to
 - Friction
 - Shearing forces
 - Moisture/maceration
- Tissue breakdown is more likely with circulatory disturbances.
- The presence of infection and edema can influence the wound environment and ultimately the extent of necrosis.

NATURAL HISTORY

- Pressure injuries are “inside-out” injuries caused by soft tissue damage from unrelieved pressure on the skin, typically overlying bony prominences.
- Tissues most sensitive to pressure die first.
 - Nerve and muscle are the most sensitive to ischemia from pressure, which is why there is no muscle or major nerves between the skin and bony prominences in any area of the body.
 - Subcutaneous fat dies first in the typical pressure injury occurring over bony prominences.
 - Skin is one of the most resistant tissues to pressure. The earliest changes seen in the skin (ie, swelling and erythema of stage 1 pressure injuries) generally reflect injury to the tissues beneath.
 - Skin breakdown without underlying tissue loss (stage II) is generally due to

shearing, friction, and maceration and not pressure per se.

- The tissue type most resistant to pressure is fascia, which has very low metabolic demands.
- “Iceberg effect”: by the time that there is any evidence of pressure injury in the skin, there is significant tissue destruction beneath; the skin findings are only the “tip of the iceberg.”
- Although pressure injuries are typical in debilitated, immobile, and/or insensate patients, they are not inevitable and indeed should be preventable in most situations.
- Prevention is directly related to educating and motivating patients and or caregivers in
 - Recognizing risks in various situations
 - Pressure-relief training
 - Relieving pressure every 15 minutes when seated or for 5 minutes every 2 hours when in decubitus position will generally prevent pressure injuries.
 - Providing resources (eg, cushions for seats)
 - Compliance
- Change in caregivers and/or intermittent psychological disturbance (such as depression) correlate with pressure injury development and recurrence.
- Evaluation and coordination with a rehabilitative team preoperatively leads to the least incidence of recidivism.^{5,6}

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients at risk
 - Patients with diminished mobility
 - Paralyzed patients
 - Spinal cord injury, disease, or dysfunction
 - Patients under anesthesia or deep sedation during surgery or undergoing procedure or treatment requiring prolonged immobilization (eg, ECMO)
 - Patients requiring others to move them
 - Patients with quadriplegia
 - Patients who are debilitated due to cerebral dysfunction (stroke, intoxication, infection)
 - Debilitated patients in acute care and long-term care facilities
 - Patients with diminished sensation
 - Spinal cord injury, disease, or dysfunction

- Peripheral neuropathy
- Assess for muscle spasticity, which increases the risk of shearing forces and friction and postoperative healing issues if not controlled.
- Assess for joint contractures, which make avoiding pressure on bony prominences very difficult for health care providers.
- Assess for tunneling and pseudobursa formation.
- Assess for involvement of joint spaces and other adjacent structures.
- Assess for bone exposure.
- Assess for infection: soft tissue and bone.
- Assess for urinary tract infections, in patients with spinal cord dysfunction.
- Assess patient and caregiver knowledge, home resources, likelihood of being compliant, and potential social/psychological issues, all of which can affect incidence of recurrence.

IMAGING

- X-rays are helpful for assessment of osteoporosis, fractures, and heterotopic ossification.
- Radionuclide bone scans are helpful in assessing activity of heterotopic ossification.
- MRI is the best diagnostic imaging to evaluate for acute osteomyelitis; however, bone biopsy remains gold standard for the diagnosis of osteomyelitis.
- CT scan or MRI and sinograms are helpful to evaluate for sinus tracts, fluid collections, and tunneling in the pelvis or possible involvement of rectum.

NONOPERATIVE MANAGEMENT

- Nonoperative management of pressure injuries is appropriate in patients who
 - Are prohibitive surgical risk due to comorbidities
 - Demonstrate that they would not be compliant with postoperative regimens
 - Need to be prepared for possible operative management in the future
- Optimize nutrition (sufficient protein, vitamins/minerals).
- Monitor prealbumin levels.
- Check vitamin D levels.
- Promote optimization of general medical care.
- Evaluate cardiovascular, pulmonary, and genitourinary systems.
- Promote smoking, alcohol, and drug cessation.
- Promote treatment of depression.

- Optimize wound conditions.
 - Quantitative bacteriologic assessment of wound with wound tissue biopsy
 - Pathologic assessment of long-standing (more than 5 years) wounds with wound tissue biopsy
 - Offloading/frequent turning for pressure relief
 - Air mattresses/cushioning
- Provide patient and caregiver education.
- Prevent spasticity.
 - Medical management: baclofen, dantrolene, diazepam, botulinum toxin
 - Surgical management: rhizotomy, baclofen pump, peripheral nerve blocks
- Infection control
 - Assess colonization vs infection of wound using quantitative cultures.
 - If quantitative culture shows greater than 10^5 organisms per gram, use a topical antimicrobial (eg, silver sulfadiazine, mafenide acetate, dilute hypochlorite solution).
 - If unable to control bacteria with topical, it may need surgical debridement.
 - Systemic antibiotics used for treatment of cellulitis, osteomyelitis, or joint space infections as well as for any distant infection of genitourinary or respiratory tracts
 - If repeat quantitative culture shows greater than 10^5 organisms per gram, consider additional debridement and/or change in topical antibiotic treatment prior to definitive closure.

SURGICAL MANAGEMENT

- All patients are candidates for surgical debridement, but not all patients are candidates for surgical closure.
 - Candidates for closure should demonstrate (along with their caregivers) an understanding, commitment, and motivation to prevent future injuries.
 - In addition, they must demonstrate compliance with nonoperative management (including nutrition, pressure relief, and wound care) and have the necessary resources available prior to definitive surgical closure.
 - Evidence of improvement of wounds with nonoperative management is a good indicator that patient/family are motivated, have the appropriate resources, and will likely abide by postoperative protocols.
- Surgical options for pediatric patients and adult patients are similar.
 - Consider whether child (or adult) has the potential to become ambulatory in

the future when deciding best reconstructive option.

- Optimize nutrition, minimize muscle spasms, and obtain bacteriologic balance in the wound prior to definitive surgical closure.
- Ensure that adequate debridement is performed prior to definitive closure.

Preoperative Planning

- Preoperative evaluation and coordinating with the multidisciplinary rehabilitative team that will care for patient postoperatively has been shown to minimize recurrence.^{5,6}
- Assess location, size, and depth of wound.
 - Is there a pseudobursa that needs resection?
 - Is there a bony prominence that needs to be flattened?
 - Is there evidence of osteomyelitis?
 - Does it need to be resected?
 - Is there heterotopic ossification?
 - Does it need to be resected?
- Review previous surgical interventions and incisions.
- Consider ambulatory status of the patient.
- Plan closure with skin graft or flap depending on location of wound and goal.
 - If the wound is amenable to closure with a graft, is it the best technique to use or would a flap give a better result?⁷
 - If a flap is chosen; determine whether it should be a muscle, musculocutaneous, fasciocutaneous, cutaneous, or perforator flap.
- Plan obliteration of anticipated dead space.
- Plan flaps with the understanding that recurrence of pressure injuries is frequent and the ability to reuse a flap is frequently helpful.

Positioning

- Need to ensure that all bony prominences and pressure points are protected and padded to avoid creating new pressure injuries during surgery.
- Posterior wounds are generally best positioned prone but may be put in lateral decubitus position if needed.
 - Airway needs to be secured well.
 - The hips should be flexed for inset of thigh-based flaps.
- Ischial injuries may be addressed in lithotomy position.

Approach

- Adequate debridement includes removal of the pseudobursa and all necrotic, devitalized, and infected tissue as well as removal of all scars if possible.
- Preliminary bedside debridement can be helpful to obtain tissue cultures and decrease the wound burden of nonviable tissue.
 - Long-standing (greater than 5 years) wounds should be biopsied to rule out Marjolin ulcer.
- Bedside debridement is rarely adequate because of inability to remove all dead tissue without too much bleeding or pain in patients with sensation.
- The use of methylene blue dye during operative debridement will assist in removing pseudobursa and ensuring all surface tissue is removed, especially in irregular wounds with tracts and tunneling.
- Bony prominences should be flattened.
- All nonbleeding infected bone should be removed.
- Pre- and postdebridement tissue cultures should be obtained of soft tissue and bone.
- Many patients require more than one operative debridement to optimize the wound or allow for optimization of a systemic condition prior to definitive surgical closure.
- Once a wound is adequately debrided, determine if the next goal is to close the wound or to reconstruct the part.

TECHNIQUES

- Closure should be preceded by adequate debridement.
- The techniques below describe typical debridement techniques and examples of closure or reconstructive options utilizing standard principles and concepts.

■ Surgical Debridement

- Paint the wound (and/or inject sinuses) with methylene blue dye to stain the pseudobursa, granulation tissue, and other surface tissue to ensure complete removal (**TECH FIG 1A,B**).
 - This is particularly important in irregular wounds with tracts and tunneling.
- An incision should be made through normal skin circumferentially around

the wound (**TECH FIG 1C**).

- Incision should be carried down through normal subcutaneous tissue, beneath all blue-stained as well as indurated tissue and scar converging on any bony prominences if present.
- Wounds that have bony prominences such as ischial and trochanteric pressure injuries should have these prominences flattened, typically with an osteotome.
- Pre- and postdebridement samples of soft tissue and bone should be sent for quantitative bacteriologic assessment.
- Postdebridement bone biopsy samples should be sent for pathologic assessment to rule out osteomyelitis.
- The entire debrided wound should be sent for pathologic assessment, especially in long-standing chronic ulcers (**TECH FIG 1D**).

TECH FIG 1 • Debridement. **A.** Sacral and trochanteric pressure injuries after bedside

debridement. **B.** After application of methylene blue to help guide debridement. **C.** Immediately after excisional debridement of sacral and trochanteric pressure injuries. **D.** Five weeks later after nutritional repletion.

■ Sacral Pressure Sore Closure

- Sharp surgical redebridement into normal tissue as described above.
- Determine location of perforator vessels with handheld Doppler.
- Large left-sided inferiorly based rotation perforator flap is designed (**TECH FIG 2A**).
- Incisions are made and the flap is elevated above the muscle to large medial perforator (**TECH FIG 2B,C**).
- Skin overlying the left gluteal muscle rotated clockwise to close most of the wound and contralateral skin overlying the right inferior gluteal muscle rotated to close the rest without tension (**TECH FIG 2D**).

TECH FIG 2 • Sacral and trochanteric pressure injuries. **A.** Design of the left superior gluteal perforator fasciocutaneous rotation flap. **B.** Flap elevated. *Arrow* points to perforator. **C.** Design of the right inferior gluteal myocutaneous flap. **D.** Sacral and right trochanteric pressure injuries closed. *Arrows* demonstrate direction of skin rotation.

■ Ischial Pressure Sore Closure

- Sharp surgical debridement into normal tissue as described above.
- Previously used left posterior thigh flap, based on the descending branch of the inferior gluteal artery, was re-elevated and transposed, and along with a gluteal perforator rotation flap, the left ischial pressure sore was able to be closed.
- Right ischial pressure sore closed with a crescent VY inferior gluteal

myocutaneous flap with distal muscle extension to be “tucked” underneath to fill dead space (**TECH FIG 3**).

TECH FIG 3 • Bilateral ischial pressure injuries. **A.** Left side recurrent, note design of previous posterior thigh flap. **B.** After debridement. **C.** Design of right ischial closure with inferior gluteal myocutaneous flap with the skin designed to be moved as a V-Y and muscle extension to be folded under to fill dead space. **D.** Inferior gluteal muscle before it is folded under to fill

dead space. **E.** V-Y closure of cutaneous portion of flap. **F.** Six-month follow-up of left ischial closure by transposing previous posterior thigh flap and right with inferior gluteal myocutaneous flap.

■ Medial Inframalleolar Perforator Flap

- After determining location of perforator vessels and direction of venous flow, the flap can be designed with the anticipated pivot point centered over perforator vessels.
- Incision is made and carried down through the subcutaneous tissue.
- The flap is elevated toward the perforator.
 - Transposition of flap is less than 90 degrees, so the perforator vessels do not need to be skeletonized.
- The flap is transposed and inset.
- Donor site is closed with a split-thickness skin graft (**TECH FIG 4**).

TECH FIG 4 • Pressure injury of left medial heel. **A.** Initial eschar. **B.** After debridement. **C.** Design of medial inferior malleolar perforator flap. **D.** Elevation of flap (*arrow* points to perforator). **E.** Flap transposed and donor site closed with a skin graft. **F.** Stable closure demonstrated 6 months later.

■ Skin graft

- Flaps are not required for all wounds.
- A well-vascularized wound bed may be closed with skin grafts or allowed to close by secondary intention (**TECH FIG 5**).

TECH FIG 5 • **A.** Right lateral malleolus and heel pressure injuries. **B.** After debridement **C.** Five weeks after wound care and nutritional repletion wound closed with a skin graft. **D.** Six months stable coverage of malleolus. Heel closed by secondary intention.

■ Propeller flap

- After debridement as described above make an incision to verify location of the perforator.
- Elevate the flap and skeletonize the perforator.
- Turned 180 degrees and flap inset (**TECH FIG 6**).

TECH FIG 6 • **A.** Left elbow pressure sore. **B.** After debridement and incision to verify location of

perforator. **C.** Propeller flap elevated. **D.** Propeller flap turned 180 degrees. **E.** Flap inset. **F.** Stable closure demonstrated 6 months later.

PEARLS AND PITFALLS

Debridement	■ All patients are candidates for surgical debridement, but not all patients are candidates for surgical closure. ■ Wide local debridement prior to definitive surgical closure is necessary for successful pressure ulcer coverage.
Methylene blue	■ Paint wound and inject sinuses to help facilitate adequate debridement.
Infection	■ Obtain bacteriologic balance prior to definitive closure. ■ Assess soft tissue and bone by tissue biopsy cultures.
Flaps	■ Flaps should be well vascularized, inset without tension, and able to obliterate dead space. ■ Do not burn bridges with closure options; consider flaps that can be reused if recurrence occurs.
Skin grafts	■ Skin grafts tolerate pressure but do not tolerate shear forces well.

POSTOPERATIVE CARE

- Use perioperative antibiotics only, unless postdebridement cultures are positive.
- Closed suction drains should be used to help obliterate dead space, improve tissue apposition, and minimize fluid collections.
- Patients should be nursed on a specialized mattress, air fluidized bed, or in prone position for 3 to 6 weeks postoperative.
- Gradually progress advancement of activity.
- Control/prevent spasticity.
- Continue optimization of nutritional support.

OUTCOMES

- Despite optimization, recurrence rate is high for many patients.

- Minimize recurrence by working with multidisciplinary rehabilitative team preoperatively and postoperatively.^{4,5}

COMPLICATIONS

- Acute wound breakdown is generally related to poor surgical planning, with either ischemic flap edges or excess tension on suture lines or a complication such as hematoma.
 - Hematomas are thought to be more common in patients with spinal cord injury due to loss of sympathetic vascular tone and inability to vasoconstrict blood vessels.
- Subacute recurrence (wound breakdown) is generally related to failure to obliterate dead space with fluid collection, which may subsequently get infected.
- Delayed recurrence is generally related to inadequate compliance with pressure preventing protocol.

CHAPTER Vascular Lesions

Benjamin C. Garden and Jerome M. Garden

DEFINITION

- Vascular lesions can be classified into two main categories: proliferative and malformations.¹
- Vascular proliferative lesions are characterized by a proliferation of blood vessels.
 - Infantile hemangiomas are the most common form of vascular proliferative lesions.
 - Other vascular proliferative lesions include kaposiform hemangioendotheliomas, tufted angiomas, and pyogenic granulomas.
- Vascular malformations are characterized by vessels with abnormal structure and normal endothelial cell turnover. Types of malformations include capillary, venous, lymphatic, arterial, and arteriovenous malformations (AVMs).
 - Capillary malformations include nevus simplex (salmon patch) and nevus flammeus (port-wine stain, PWS).
 - Venous malformations (VM) are a fairly common slow-flow type of vascular malformation present at birth. Various names used to describe these lesions include venous angioma and cavernous angioma.
 - Lymphatic malformations (LM) are composed of interconnected lymphatic channels.²
 - Older terminologies used include cavernous lymphangioma, lymphangioma circumscriptum, and cystic hygroma.
 - LM can be further differentiated into macrocystic and microcystic depending on the size of the involved channels.
 - AVMs are rare vascular malformations consisting of both arterial and venous

components with AV shunting.²

ANATOMY

- Vascular lesions may occur on any cutaneous surface but are most commonly found on the head and neck.
- Hemangiomas have been noted to have a nonrandom distribution, with the majority of lesions occurring on the central face at sites of development fusion.³
- Capillary malformations are often, but not always, unilateral.

PATHOGENESIS

- Hemangiomas are thought to occur due to a first-trimester developmental error regarding angiogenesis or a result of embolized placental cells. There is a suggested autosomal dominance inheritance.⁴
- Although their exact cause is unknown, PWSs evolve due to a progressive ectasia of the superficial vascular plexus. This progression is likely due to an abnormal neural regulation of blood flow. PWSs have significantly less nerve density and a higher vessel to nerve ratio.⁴

NATURAL HISTORY

- Infantile hemangiomas become evident in the first weeks of life and exhibit a proliferative phase, with continued growth, until around 8 to 12 months. This is followed by a plateau phase, followed by a period of spontaneous regression as the lesion involutes.
- Initial involution is usually noted with a color change from the original bright red to dull red or gray.
 - It is estimated that completed involution occurs at a rate of 10% per year, such that 30% have involuted by 3 years of age, 50% by 5 years of age, and greater than 90% by 9 to 10 years of age.³
 - These lesions occasionally have residual changes, including telangiectasias, atrophy, scarring, or fibrofatty material.
- Ulcerations occur in 5% to 13% of infantile hemangiomas.
 - Most frequent locations include the lip, perineum, and intertriginous areas.
 - Ulcerations are painful, increase the risk of infection, and can cause scarring and textural changes.³
- Vascular malformations tend to be present at birth and persist for a lifetime.
- PWS may darken progressively over many years, and occasional lesions

develop secondary vascular blebs on their surface. They may also become hypertrophic later in life.

- VMs are present at birth but may not become obvious until later in life. Occasionally, a patient first notices the lesion after trauma to the overlying area. In those cases, the trauma may cause the underlying vessels to temporally enlarge allowing the patient to notice it for the first time.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The preoperative evaluation for patients with vascular lesions includes a detailed history and exam to determine the type of lesions and to assess the risks of the patient having any associated complications or syndromes.
- Infantile hemangiomas may occur as superficial, deep, or mixed lesions.
- Superficial lesions tend to appear as bright red nodules or plaques (**FIG 1A**).

FIG 1 • **A.** Superficial infantile hemangioma. **B.** Port-wine stain. **C.** Venous malformation. **D.** Mixed microcystic lymphatic and venous malformation.

- Deep hemangiomas are subcutaneous nodules, and usually present with an overlying blue hue, venous network, or telangiectatic vessels.

- Hemangiomas in certain locations may suggest a higher probability of complications or associated findings.³
 - With periorbital hemangiomas, an ophthalmologic examination is generally recommended in many cases.
 - Larger lesions of the beard area require evaluation for potential airway obstructions.
 - Hemangiomas on the tip of the nose, the lip, and the parotid areas can have very slow involution periods.
- PWSs are normally easy to recognize with their well-defined red macular stains (**FIG 1B**). They do not proliferate, but will grow proportional to the child's growth. Patients with PWS should be assessed for any associated syndromes that would necessitate additional referrals.
 - The most common syndrome is Sturge-Weber syndrome (SWS), which most commonly occurs with a PWS occurring in the distribution of the ophthalmic branch of the trigeminal nerve (V1).
 - PWS can be associated with many other syndromes including Klippel-Trenaunay, Parkes-Weber, Proteus, Cobb, Rubinstein-Taybi, and Beckwith-Wiedemann syndrome.
- VMs usually present as blue to purple nodules in the skin (**FIG 1C**). They may have prominent surrounding veins and calcified phleboliths within the lesion. These lesions may expand with dependent drainage of venous blood; this may be elicited by placing the patient in the Trendelenburg position or by performing the Valsalva maneuver.²
 - Most VM are asymptomatic, although they may occasionally become painful in association with their gradual enlargement and pressure on surrounding structures.
 - They may be found in association with syndromes, including Maffucci and blue rubber bleb nevus syndrome.
- Macrocystic LMs, sometimes referred to as cystic hygromas, present as large, translucent masses under normal-appearing skin. Microcystic LM usually present as erythematous to flesh-colored papules, which may be somewhat translucent, and have traditionally been compared to the appearance of frog spawn (**FIG 1D**).
- AVMs may be clinically pulsatile and warm and have a thrill. They present as a vascular stain at birth, with increasing erythema and size with age. They can spontaneously bleed.

IMAGING

- One should strongly consider doing a liver MRI in those patients having five or more hemangiomas due to the increased potential of having visceral lesions.³
- Large segmental facial hemangiomas should prompt imaging to assess possible PHACES syndrome:
 - *Posterior fossa malformations*
 - *Hemangiomas*
 - *Arterial anomalies*
 - *Coarctation of the aorta*
 - *Eye abnormalities*
 - *Sternal or supraumbilical raphe*
- Perineal hemangiomas should prompt evaluation for PELVIS syndrome:
 - *Perineal hemangiomas*
 - *External genital malformations*
 - *Lipomyelomeningocele*
 - *Vesicorenal abnormalities*
 - *Imperforate anus*
 - *Skin tags*
- In patients with a PWS, imaging may be necessary if there is concern for a related syndrome, such as SWS. MRI is the preferred screening modality of SWS. Patients with a vascular malformation located in the midline lumbar location may have an underlying AVM, as seen in Cobb syndrome, which would be imaged by an MRI.
- VM can be confirmed or the depth of involvement can be ascertained with MRI with and without contrast.

NONOPERATIVE MANAGEMENT

- Generally, appropriate treatment for infantile hemangiomas is nonintervention.⁵ However, in those lesions where there is high visibility, social concern or functional impairment, as well as complications such as ulceration, infection or bleeding, therapy may be warranted.^{4,6}
 - Topical timolol can be useful in the treatment of superficial hemangiomas.
 - Treatment using oral propranolol may be indicated for functional impairment, significant ulceration, or lesions with potential for significant disfigurement.
 - Topical wound care is also necessary for ulcerated lesions.

SURGICAL MANAGEMENT

- Lasers are designed to deliver energy precisely into the target chromophore with minimal damage to surrounding tissue.
- To keep the laser from causing widespread damage to other tissues, the laser exposure should occur faster than the amount of time it takes for the heat to extend significantly beyond the target.
- Safe and effective heating occurs using a pulse duration equal to or less than the target's thermal relaxation time (TRT). TRT is the amount of time for the tissue to lose half the heat gained from the laser.
 - For PWS, the target venules have a TRT of tens of milliseconds.⁴
- Surgical intervention with lasers for hemangiomas should be used cautiously but can be very helpful, especially for lesions in areas of high visibility or areas of high risk for ulcerations, such as the anogenital area.
- Laser treatment of ulcerated hemangiomas can lead to decrease in pain and more rapid healing. However, care must be taken because aggressive laser treatment can occasionally induce ulcerations.
- Lasers can also be used for the treatment of involuted lesions with residual telangiectasis or residual dermal vascular involvement.⁷
- Lasers can be used successfully in conjunction with propranolol.⁸
- Excisional surgery of hemangiomas can lead to a more unsatisfactory result than an untreated lesion, and therefore, the risks and merits of surgical intervention should be discussed with the family and surgical removal performed on a case-by-case basis.
- PWS should be treated with laser surgery as early as possible with the natural evolution of these lesions to become more hypertrophic over time. Additionally, children younger than 1 year seem to have the most effective lightening and require fewer treatments than older patients.⁴
- One should note that laser surgery can be helpful in treating PWS, but some PWSs can partially recur over an extended period of time with aging.
- PWS lesions on the periorbital region, midforehead, lateral cheeks, chest and proximal arms respond best to treatment, whereas the other areas are more resistant.⁶
- The superficial components of VMs may be treated with laser therapy. However, more extensive malformations may be treated via sclerotherapy prior to eventual surgical excision.²
- Carbon dioxide lasers used in a nonfractional mode can be used to treat the

superficial blebs of lymphatic lesions, vaporizing the tissue nonselectively and sealing the lymphatic channels.

- Embolization and surgical resection are the mainstay of treatment of AVMs.

Preoperative Planning

- A pretreatment consultation is advisable to discuss potential lesional response, number of treatments, expected and potential adverse effects, and aftercare.
- Visual examination of lesion and of patient skin type assists in planning of laser treatment. Optimal coherence tomography, three-dimensional photography, and reflectance spectrophotometry are newer technologies that are being evaluated to assist in objective quantification of preprocedure and postprocedure lesional depth, volume, and color.⁹
- Patients should be advised to practice strict sun protection for at least 4 to 8 weeks prior to treatment. Treatment of a patient with a tan can result in permanent hypopigmentation.
- Patients with darker skin are at risk for hypopigmentation and hyperpigmentation.
- An assessment of the child's ability to tolerate treatment should be made prior to choosing an anesthesia option. Options include topical, intralesional, and general anesthesia.
 - Although topical anesthetics such as topical liposomal lidocaine and a eutectic mixture of local anesthetics (EMLA cream, 2.5% lidocaine/2.5% prilocaine) have been used, topical anesthetics may cause significant blanching of the vascular lesions, making them more difficult to be effectively treated with the laser, as there is less hemoglobin to act as a target chromophore.
 - Special care should be used with prilocaine in infants as it is associated with an increased risk of methemoglobinemia.
 - Most infants less than 1 year of age are restrained and treated without general anesthesia.
 - General anesthesia is appropriate in older children. However, general anesthesia also may be associated with blanching of the lesion. Care should be taken to limit the use of the general anesthetic to as low a dose as safely possible to reduce blanching.^{6,9}
- Photographs should always be taken before the initial treatment. Photographs before subsequent treatment sessions to the same area are at the discretion of

the clinician.

- Flammability is a risk when using lasers. Water or clear non-alcohol-based viscous lubricants can be used to diminish singeing terminal hairs.

Positioning

- The patient should be placed in a position that allows the clinician to manipulate the laser handpiece without difficulty.
- Infants and young children, who will be undergoing the treatment without general anesthesia, are recommended to be held and restrained with a bear hug by a parent or assistant. Placing an infant in a papoose may be of help in addition to immobilization by an assistant.

FIG 2 • A. Overlapping white gauze held with a firm hand should be used to cover the periorbital area in young children in whom the protective eye glasses would be too large. **B.** Globe eye shields should be used when lasering close to the orbit. Note the postoperative purpura from the pulsed dye laser.

- Everyone present must use appropriate eye protection during laser treatment.

- Most glasses and goggles may be too large for small children.
- Overlapping white gauze held with a firm hand should be used to cover the periorbital area, as these will reflect laser light (**FIG 2A**). The gauze should be moistened with water if used with general anesthesia. Pressure should be placed on the orbital rim and not on the eye itself.
- Globe eye shields must be used if lasering close to the eye (**FIG 2B**).

Approach

- The most commonly used laser for superficial or ulcerated hemangiomas is the pulsed dye laser (PDL). Suggested settings are dependent on the various chosen parameters and may include wavelengths of 585 to 595 nm, fluences of 4 to 8.5 J/cm², pulse durations between 0.45 to 3 ms, spot sizes of 5 to 10 mm, and a concomitant cooling device.
 - Deeper parts of the lesion can respond to long-pulsed Nd-YAG or alexandrite lasers, although there is a higher risk of scarring and pigmentary complications.
 - The PDL is the most commonly used laser for PWS treatment. General settings to be used could include 585 to 595 nm for wavelength, 5.5 to 11 J/cm² for fluence, 0.45 to 3 ms for pulse duration, and 7 to 12 mm for spot size. Lasering is most safely performed in combination with epidermal cooling (Table 1).
 - A larger spot size allows the laser beam to penetrate deeper into the lesion. However, lower fluences are used for larger spot sizes to maintain a high safety profile.
 - Changing the pulse duration may allow targeting of different sized vessels. Treatment often begins at 1.5 ms, and this can be adjusted down to 0.45 ms and up to 3 ms. Lower fluences are required for shorter pulse durations.
 - PWS have a nonuniform response to laser surgery, likely due to variously sized blood vessels, different flow rates, and different depths of involvement.
 - One should not use a cookbook approach to the settings used. Each lesion is unique. It is strongly recommended that test sites be placed with each patient. Or, if there are overriding reasons not to place test sites, initially use only very low-energy parameters for the first treatment, especially in infants. If one is in such a situation that limits the placement of test sites, one may treat a larger area at a low-energy setting and place discreet test sites with slightly higher settings during the first treatment session.
-

Table 1 General Settings Used With Pulsed-Dye Laser

Vascular lesion	Wavelength (nm)	Fluence (J/cm ²)	Pulse Duration (ms)	Spot Size (mm)
Hemangioma	585–595	4–8.5	0.45–3	5–10
Port-wine stain	585–595	5.5–11	0.45–3	7–12

- For older patients who prefer a treatment without purpura, one can use an intense pulsed light (IPL) device (**FIG 3**). These systems are less safe around the eyes and with higher skin types. Each IPL system is manufactured differently and is applied in a unique approach appropriate to the particular system. It is recommended to be very familiar with the device that is to be used and always place test sites.

FIG 3 • Use of an intense pulsed light (IPL) device on a partially treated port-wine stain.

TECHNIQUES

■ Test Sites

- One should perform test sites prior to treatment of the entire lesion. In larger lesions, especially over multiple anatomical regions, test pulses should be performed over the various regions and clinical lesional variations. Patients are evaluated dependent on their age anywhere from 4 to 8 weeks after test site placement to assess response of the test sites.

■ Laser Treatment of Vascular Lesion

- Once the clinician has determined appropriate settings from the test pulses, one can treat the entire lesion. If the test site outcomes were not decisive, one should not hesitate to place additional test sites with even the same and other parameters until one feels comfortable proceeding. One often treats different anatomical regions with different parameters. Even the same anatomical region may be treated with different parameters dependent on symmetry of lesional involvement.
- In those patients having ill-defined borders and especially for those patients receiving general anesthesia that induces fading of the lesions, prior to treatment, it may be helpful to outline the borders of the lesion. Place the outline marker slightly beyond the margin of the lesion because the marker material itself may absorb laser energy resulting in undesired damage to the skin.
- The laser handpiece should be pressed gently, perpendicularly, against the skin (**TECH FIG 1**). Avoid aiming tangentially at the skin, as this may alter the fluence and the cooling device effectiveness.
- To regulate the amount of laser energy impacting the skin, thus reducing the chance of undesired adverse effects, only single passes are generally placed with pulsed dye laser and intense pulsed light (IPL) systems. Pulse overlap should also be avoided or at least limited to less than 10% overlap.
- Throughout the treatment, the clinician should always be monitoring the tissue for the desired tissue changes such as tissue darkening or edema. When there is any deviation, stop the procedure and check the laser and parameters or reassess the lesional area being treated. In those patients who are not anesthetized and are old enough to give reliable feedback, a change in pain level is also an indicator that parameters should be reconsidered. Ask the patient to inform the clinician if there is any change in baseline procedural discomfort.

TECH FIG 1 • The laser handpiece should be pressed gently, perpendicularly, against the skin. Note the physician is protecting the patient's eye with white gauze.

PEARLS AND PITFALLS

Eye protection

- For children, cover the periorbital area using overlapping white gauze held firmly.
- Pressure should be placed on the orbital rim and not on the eye itself.
- If there is use of inhalation anesthesia, the gauze should be thoroughly wetted with water or saline. Tape or similar nonflammable material may be placed on the closed eyelid to ensure it remains closed.
- With any lasering near or into the orbital rim, a full global eye shield should be placed.

Clinical endpoint

- Always pay attention to tissue response to each pulse.
- Any deviation from previous responses or blistering or vesiculation is a cause of serious concern, mandating stopping the procedure and

	reassessing the laser and parameters.
Therapeutic outcome	■ Ideally, total lesional resolution is desired. With port-wine stain vascular malformations, this is achieved only in a small minority of cases after a series of many treatment sessions. ■ If after an initial trial no further lesional regression is accomplished, it is probable that one has achieved the maximum lesional reduction possible with the current therapeutic approach. Either another approach should be tested or therapy should be suspended, and the family should be informed of the ineffectiveness of further therapy using the current approach.
Skin color	■ The higher the skin type the greater is the absorption of laser energy by melanin in the epidermal layer and the increased chance of cutaneous damage resulting in permanent hypopigmentation. ■ This concern is greatly enhanced if the patient has additional coloring from the sun. Since even a modest amount of darkening from the sun is associated with a significant increased risk, do not treat patients who have any appreciable color from the sun. Wait for it to fade.

POSTOPERATIVE CARE

- After treatment, all patients experience local swelling and discomfort. The discomfort is transient with the intensity dramatically reducing over the first 30 to 60 minutes. Ice packs, cooling gels, and nonsteroidal anti-inflammatory medications may minimize discomfort.
- Patients should practice proper sun protection for weeks after the treatment to minimize risk of pigmentary changes.
- Emollients should be applied routinely until clearing of the immediate postlaser changes.
- Topical antibiotics should be initiated if crusting or scabbing occurs, as these can raise risks of secondary bacterial infection.
- Postadjuvant antiangiogenesis therapy is currently being evaluated. Treatment with topical imiquimod 5% and topical rapamycin in between laser treatments has been shown to prevent reformation and reperfusion of blood vessels in small trials.^{10,11}

OUTCOMES

- Approximately 20% of PWS can be lightened completely or almost completely with the PDL. About 70% will lighten by more than 50% and about

10% to 20% of lesions will only respond minimally.¹²

- For best results, vascular lesions will require multiple treatments. Very rarely does a lesion clear after a few sessions. Typically, lesions would be treated for at least 8 to 10 treatments at a minimum of 4- to 12-week intervals.
- More resistant or hypertrophic PWSs may not respond to PDL and may be better suited for treatment with longer wavelength lasers. Proven lasers include the long-pulse alexandrite (755 nm), long-pulse 1064 nm Nd-YAG, and dual 595 nm/1064 nm lasers. These lasers are only recommended for skilled laser surgeons, as there is a very small therapeutic window, and the risk of scarring is higher.^{4,6,9}

COMPLICATIONS

- Skin darkening usually will develop immediately with PDL treatment and may persist for 10 to 14 days.
- Transient erythema and swelling typically persists for 4 to 8 days with the PDL and less with the IPL.
- Blistering and crusting can also develop, more commonly with higher fluences or with overlapping pulses.
- Transient or permanent hyper- and hypopigmentation can occur, especially in darker-skinned patients and if one treats patients with a tan.
 - Pigmentary risks can be reduced in darker skin types with using appropriate epidermal cooling, longer pulse durations and lower fluences. Treatment efficacy is also likely to be reduced when using longer pulse durations and lower fluences.
- Alopecia can occur if using lasers in areas that have pigmented hairs. Care, especially over the eyebrows, is necessary to prevent permanent hair loss.
- The risk of scarring after PDL treatment of PWS is very low (less than 1%). These risks can be minimized by using test sites.

CHAPTER Laser Burn Scar Revision

C. Scott Hultman and Yuen-Jong Liu

DEFINITION

- Mortality from burn injury has markedly decreased in the second half of the 20th century as wound sepsis, wound coverage, kidney failure, and shock have been largely overcome.
- Burn injury is the result of high-energy transfer to a significant surface area of the skin or soft tissues and can be categorized by the form of energy:
 - Contact with high temperature solids (contact), liquids (scald), or gases (flame)
 - Contact with low temperatures (frostbite)
 - Exposure to chemicals (acids, alkalines, or other caustic reagents)
 - Electricity
 - Friction or abrasion
- Burn wounds frequently heal in the form of hypertrophic scars, which hamper functional and aesthetic outcomes.
- Symptoms include pruritus, burning pain, and hyperesthesia, which may be treated with antihistamines, narcotic analgesics, and non-narcotic analgesics.
- Functional deficits may vary from tightness or tethering of the surrounding skin to contractures that limit range of motion.
- Hypertrophic burn scars may be erythematous due to hypervascularity.
- Treatments include occupational therapy, physical therapy, compression garments, moisturizing agents, sunblock, and scar massage.^{1,2}
- Evidence for the efficacy of laser therapy in the treatment of hypertrophic burn scars is now well documented in individual cohort studies,³ review articles,⁴ and a rigorous meta-analysis of 28 well-designed clinical trials.⁵

- The exact biologic mechanism for improvement has yet to be elucidated, but pulsed dye laser (PDL) improves the inflammatory component of hypertrophic burn scars, which have excess pathologic vascularity, whereas fractional carbon dioxide (CO₂) laser improves remodeling of dermal collagen, which is disorganized and abnormal in hypertrophic burn scars.
- Best practices involve six to eight laser sessions, performed every 4 to 6 weeks, using a combination of these two lasers, plus on occasion the Alexandrite laser, to ablate hair follicles in cases of chronic folliculitis of the burn scar.
- Substantial, rapid improvement in hypertrophic burn scars is now observed through objective measures, such as the Vancouver Scar Score (height, erythema, pliability), as well as subjective reports, such as the UNC 4P Scar Score (pruritus, paresthesias, pliability, and pain).⁶
- A major benefit to both the patient and the payer is that multiple, minimally invasive laser sessions may decrease or prevent the need for more complex and more invasive surgical procedures, decreasing patient risk, reducing overall cost, and potentially achieving outcomes not previously possible.

ANATOMY

- Burn scars may affect any part of the body.
- Hypertrophic scars across joints may cause contracture.
- Contractures on the face may interfere with competence of the eyelids or the mouth.
- Burn scars are especially disfiguring on the face due to its high aesthetic importance.
- Neuropathic pain may be observed in burned areas, grafted regions, and even donor sites.

PATHOGENESIS

- The incidence of hypertrophic scarring after burn injury ranges from 5% to 40%, depending on anatomic location, depth of burn, method of closure, and genomic response to healing.
- Hypertrophic scarring and contractures can develop in burn scars that heal by secondary intention or re-epithelialization, in split-thickness skin grafts over excised burns, along the seams of full-thickness grafts, and in donor sites that had delayed healing, due to infection of excessive depth of harvest.
- Hypertrophic scars may be associated with an imbalance of collagen types 1

and 3, as well as TGF beta 1 and TGF beta 3.

- Hypertrophic scarring can be viewed as an abnormal physiologic response after wound closure, in which collagen deposition and angiogenesis continue beyond their desired end points.

NATURAL HISTORY

- Neuropathic symptoms, such as pruritus, searing pain, hyperesthesias, and paresthesias, are a source of frustration for the patient, can limit quality of life, and may prevent return to school, work, and social functions.
- Hypertrophic scarring may cause disability ranging from minor discomfort to joint contracture.
- Hyper- or hypopigmentation, erythema, and abnormal texture may cause the burn scars to be aesthetically unacceptable.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Complete patient history should be elicited, focusing on the type of energy delivered: scald, electrical, flame, contact, chemical, cold, friction, abrasion, or other.
- Previous treatments and their effects should be noted, including skin grafting, laser treatments, topical scar treatments, moisturizing agents, sunblock, systemic medications, occupational therapy, physical therapy, compression garments, and massage.
- The patient should have had no significant improvement in symptoms for at least 3 months on maximal medical therapy.
- Relative contraindications to laser therapy include connective tissue disorders, utilization of systemic steroids or immunosuppressive medications, and chemotherapy or radiation therapy. Patients with moderate to severe lymphedema should also be treated with caution, as healing from ablative lasers may be delayed.
- Complete physical exam should be performed, focusing on the burned area, noting whether it is a native burn scar or burn scar after skin grafting.
- The burned areas should be well healed without open wounds or evidence of cellulitis.
- Total body surface area of the burn injury should be noted, as extremely large areas should be staged, in terms of laser treatment.
- Functional deficits should be recorded, such as loss of range of motion or loss of sensation.

- Aesthetic concerns should also be considered, especially in burns of the face and the hands.
- The patient's Fitzpatrick skin type should be documented, and this will advise the initial energy settings for the laser.
- Photographs are useful for insurance submission and to track progression of the scar between laser treatments.

IMAGING

- Imaging is not required. However, medical photography is often needed for preauthorization from insurance companies.
- For patients enrolled in a clinical trial, other imaging modalities might be helpful to measure extent of hypertrophic scarring and quantify changes:
 - Ultrasound to measure thickness of scar
 - Chroma meter to measure light-dark axis and degree of redness from erythema
 - Cutometer to measure elasticity of scar

SURGICAL MANAGEMENT

- The patient is routinely consented for a series of laser treatments, involving selective photothermolysis with the PDL, ablative resurfacing using the fractional using CO₂ laser, and either Alexandrite or diode lasers to rupture hair follicles.
- A series of 6 to 8 sessions is submitted for insurance coverage at a time, though a patient may reach maximal benefit before 6 to 8 sessions or may continue to experience symptomatic improvement beyond eight sessions.
- We strongly recommend maintaining a burn scar registry, which includes preoperative, operative, and postoperative data, which can be used for practice-based learning, retrospective and prospective cohort analysis, insurance preauthorization and payment, and medical-legal documentation.
- We recommend working with a board-certified anesthesiologist who has completed additional specialization in pediatric anesthesia or has significant clinical experience with children and has expertise in ambulatory and office-based anesthesia.
 - Multimodal anesthesia has been shown to significantly decrease patient pain, need for intravenous opioids during recovery, and time to discharge from the postanesthesia care unit.⁷
- Patients must be treated in an accredited surgery facility, which can include a

hospital-based ambulatory surgery center and an office-based surgery facility.

- Control of airway is paramount, even with mild sedation; burn patients may have compromised airways from previous tracheostomy scars and/or prolonged intubation and mechanical ventilation.
- To maximize throughput with our practice, patients do not return until their next laser session, which is typically 6 to 8 weeks later.
- The next session serves as both the postoperative visit from the previous treatment and the preoperative visit for that day's session.
- At that time, we ask the patient for feedback about their symptoms and tailor the treatment for that day based on these observations, which can include changing the energy levels as well as type of laser used.

Positioning and Preparation

- Our burn patients usually receive a Propofol drip and boluses of fentanyl, ketamine, and midazolam as appropriate.
- The burn scar should be clean but sterile preparation is not necessary.
- Sterile drapes are not necessary.
- All operating room personnel must wear tinted eyewear for PDL or clear eyewear for CO₂ laser to protect against laser backscatter.
- The patient's eyes should be closed and covered with a saline-moistened towel.
- Fire prevention is of paramount concern for all laser cases, and patient safety protocols for reducing the potential for an oxygen-enriched environment must be followed.
 - This includes lower the inspired oxygen concentration to the lowest needed FIO₂, using room air only when discharging the laser in the head and neck region, avoiding towels or drapes that can serve as a reservoir for oxygen, and alerting all OR personnel when discharge of the laser commences.
- The lasers must be calibrated and tested on the back table, before treating the patient, to confirm that the appropriate amount of energy will be delivered.

TECHNIQUES

■ Pulsed Dye Laser

Video p8-c031_02

Anesthesia

- For small areas below the clavicles, as well as test areas, in adult patients only, no anesthesia is necessary, except for the cooling of the cryogen jet, which is administered milliseconds before the laser is discharged.
- All children, adults with large surface areas, and patients with hypertrophic scars on the face and neck require some type of anesthesia, which can range from oral anxiolytics and narcotics to TIVA (total intravenous anesthesia); general anesthesia with inhalation agents is rarely used, but patients will often benefit from a LMA (laryngeal mask airway) to control the tongue and epiglottis.
- Of note, most topical anesthetics constrict the capillary targets in the dermis, so we almost never utilize these agents, to ensure that the target receives and absorbs adequate energy for selective photothermolysis.

Laser Application

- We use a Candela V-Beam, 595-nm wavelength, PDL.
- The laser is set to 1-cm diameter circular spot size, cryogen mix of 30/20, and 1.5-ms pulse duration or pulse width (**TECH FIG 1A**).
- The energy or fluence setting is titrated to mild bruising without blistering. 6.5 J/cm^2 is a reasonable level for a patient's first session for Fitzpatrick class 1 and 2 patients. For patients with Fitzpatrick grade 3 and 4 pigmentation, acceptable starting energy settings are 4.5 to 5.0 J/cm^2 . Patients with Fitzpatrick class 5 and 6 skin types must be counseled that they are at high risk for mild blistering and hypopigmentation and should be treated with

minimal fluence, such as 3.5 J/cm².

- The energy setting for subsequent sessions is increased if the patient experiences minimal skin changes in the days following the procedure. Conversely, the energy setting is decreased if the patient experiences severe bruising, blistering, or epidermolysis in the days following the procedure.
- As the operator fires the laser sequentially over the burn scar, there should be mild overlap between successive bursts (**TECH FIG 1B**).
- Each laser burst can be expected to sting as if struck by a drawn rubber band.
- End points for titrating the fluence, in the OR, include slight ecchymosis of the skin. Immediate blistering or purpura indicates that too much energy has been applied and that reduction in fluence is required.

Wound Care

- We use topical antimicrobial ointment for several days, until bruising begins to resolve.
- Oral antibiotics and antiviral agents are almost never given, except in cases of recurrent cellulitis or frequent outbreaks of herpetic infection in the treated areas.

TECH FIG 1 • A. We typically use these settings for a patient's first PDL treatment session on our Candela V-Beam, 595 nm, PDL. The laser is set to 6.50-J/cm² fluence, 1-cm diameter spot size, cryogen mix of 30/20, and 1.5 ms pulse duration. **B.** The PDL handpiece is held so that the distance guide (*purple ring*) is flat at skin level. The treatment area of hyperemic autografted burn scar is encircled with marked *dots*. There should be mild overlap between

successive bursts.

■ Fractional CO₂ Laser

Video p8-c031_01

Anesthesia

- Fractional CO₂ laser ablation is extremely painful.
- For small areas below the clavicle, in adults who have minimal baseline neuropathic pain, topical anesthetics including lidocaine and bupivacaine mixtures can be applied for 20 to 30 minutes, to create enough anesthesia that the laser can be tolerated, when using 15 to 30 mJ/micropulse.
- However, most burn patients already have neuropathic symptoms from their hypertrophic scars, so most require at least intravenous sedation and analgesia, but total intravenous anesthesia is usually employed.

Laser Application

- We use a Lumenis UltraPulse fractional CO₂ laser at wavelength of 10 600 nm.
- The laser is set to 30 to 60 mJ/micropulse, 1- × 1-cm² square spot size, 250 to 300 Hz for the micropulses, 0.3- to 0.5-second delay between sequential firing, and 5% to 3% density in terms of tissue surface area (**TECH FIG 2**).
- Higher energies of 60 to 90 mJ/micropulse can be delivered safely, provided that density is dropped to 1%. We rarely use energy of this magnitude, expect

in very thick hypertrophic scars that require a greater depth of penetration, to yield fine, punctate, capillary bleeding. The efficacy of using such high energies has not been rigorously studied, and we cannot recommend using energy of this magnitude routinely.

TECH FIG 2 • A. On our Lumenis UltraPulse fractional CO₂ laser, initial settings consist of 30 to 60 mJ/micropulse, 1- × 1-cm² square spot size, 0.5-second delay between sequential spots, 300-Hz firing rate, and 5% density. **B.** The CO₂ laser handpiece is held so that the distance guide (translucent grey ring) is flat at skin level. The treatment area of indurated autografted burn scar is outlined by skin marker. There should be minimal or no overlap between successive bursts. An assistant suctions vaporized tissue smoke with the tip of the evacuator (purple end of plastic tubing) held a few centimeters from the laser spot to remove vaporized tissue smoke.

- While some surgeons use very high energies to treat keloids, we prefer to manage burn scar keloids by direct excision and fractionated, immediate postoperative radiation. In children, patients with keloids of the neck (where the thyroid and parathyroid glands could be in the field of irradiation), and patients with a history of XRT, we instead close the wound through complex repair, tissue rearrangement, or skin graft and then proceed with laser therapy to reduce the incidence of recurrence.
- The laser should be tested on a wooden tongue depressor, to confirm orderly and consistent ablation, evidenced by a regular pattern of burn marks on the

tongue depressor.

- As the operator fires the laser sequentially over the burn scar, there should be minimal or no overlap between successive bursts (**TECH FIG 2B**).
- An assistant should suction away vaporized tissue smoke, as this may be dense and irritating. Furthermore, the plume may contain viral particles that could theoretically infect members of the OR team. For that reason, the surgeon must wear a tight-fitting, filtered mask.
- The energy setting is titrated to pinpoint bleeding, indicative of penetration into the reticular dermis.
- Char is left in place.

Wound Care

- The treated areas are immediately dressed with a topical antibiotic ointment and cooled with ice packs.
- We routinely apply topical corticosteroids, dosed to patient weight, through vigorous massage into the fresh channels.
- Patients with a history of significant postoperative itching or pain are also treated with topical antihistamines and lidocaine, respectively.
- These pharmacologic agents are kept in contact with the treated areas with semiocclusive dressings, which are then gently and snugly wrapped with circumferential gauze, which is removed in 1 to 2 days.

PEARLS AND PITFALLS

Anesthesia

- All patients require a personalized plan, which can range from topical agents to general anesthesia, depending on patient age, location of burn scar, type of laser used, and energy applied. Almost all patients can be discharged on the day of surgery, except for those infrequent patients who may require monitoring of airway or who experience postoperative nausea and vomiting. It is critical to use only the amount of anesthesia necessary to produce the desired level of comfort.

End points

- PDL: slight bruising or reactive erythema.
- CO₂: fine punctate bleeding with reactive erythema.

	■ Diode and alexandrite: rupture of hair follicle with flash of light and audible crackle.
Complications	■ Blistering can occur with PDL, especially in patients with higher Fitzpatrick scores; this is very superficial and is treated with topical ointment until wound re-epithelializes. ■ Hypopigmentation is quite common. ■ Postinflammatory hyperpigmentation can occur with UV radiation exposure and should be treated with topical corticosteroids. ■ Allergy to topical antibiotics can occur after prolonged use of these agents and typically resolves with cessation of use. ■ Cellulitis is rare but does respond quickly to oral antibiotics, which include coverage of MRSA. ■ Wound breakdown and infarction is extremely uncommon and may be due to a combination of technical issues with too much energy delivered and superimposed infection.
Cessation of therapy	■ Most patients achieve maximum benefit after 4–6 sessions, but continued improvement can occur well beyond this series of treatments. We typically stop treatments when both the patient and provider agree that signs and symptoms have reached maximum improvement.

POSTOPERATIVE CARE

- The patient should be advised to expect reactive erythema, bruising, and occasional superficial blistering within 3 to 5 days.
- The patient should apply bacitracin ointment daily to the treated area.
- Patients must avoid sunlight to prevent UV radiation exposure.
- Postprocedure pain should be adequately covered by over-the-counter analgesics such as acetaminophen and NSAIDs.
- We do not routinely prescribe narcotic analgesics after PDL.
- The CO₂ laser is painful, and we routinely prescribe a small amount of narcotic analgesics for postprocedure pain.
- Dressings can be taken down by the family 1 to 3 days after treatment.
- Occupational and physical therapy can be started at that time.
- Compression garments can be worn when the scab formation occurs, typically 5 days after treatment.
- Children often go back to school, and adults return to work, within 1 to 2 days.

OUTCOMES

- Some degree of symptomatic improvement can be expected in all patients, though returns tend to diminish with each successive treatment (Clayton, Levi). We objectively measure improvement with the Vancouver Scar Score, in which the provider rates thickness, redness, color, texture, and pliability. Patients provide subjective feedback through the use of the UNC 4P scale, in which patients rate pain, paresthesias, pliability, and pruritus. Interestingly, patients often report continued subjective improvement, after the provider notes plateau in objective clinical findings.
- Patients who reach maximum improvement are re-evaluated in 2 to 3 months and then at yearly intervals thereafter. Children will often experience recurrence of symptoms during and after puberty and may benefit from an additional series of sessions, sometime many years later.
- One unexpected finding is that many burn patients with chronic neuropathic pain, whose hypertrophic scars have been treated with lasers, present with focal anatomic causes of their pain, such as nerve compression or neuroma formation. Laser therapies treat the generalized inflammatory and hypertrophic response, often unmasking surgically treatable causes of chronic neuropathic pain. Diagnosis of an anatomic cause can be made by clinical exam, with elicitation of a Tinel sign, as well as nerve block, which can be assisted with ultrasound guidance. If an anatomic cause is identified, then patients may undergo a combination of nerve decompression and transposition, neuroma resection with subfascial or intramuscular implantation, or fat grafting. In our experience, laser treatment of hypertrophic burn scars improves chronic neuropathic pain in 80% to 90% of patients, as defined by reduction of symptoms and de-escalation of pharmacologic regimen. In the remaining patients, 80% to 90% have an anatomic cause of neuropathic pain that is amenable to surgical intervention. One guiding observation is that over the past 10 years of treating hypertrophic burn scars with laser therapies, the more we look for discrete anatomic causes of neuropathic pain, the more likely we are to find abnormalities that respond to a combination of nerve decompression and neuroma resection. Fat grafting has also proven to be a highly successful form of treatment in refractory cases.

COMPLICATIONS

- Adverse events are minor and include hyperpigmentation, hypopigmentation, mild blistering, pain, rash, fever, and infection (Clayton).

- In our 10-year experience, involving 800 sessions per year, we have observed one case of herpetic whitlow, one case of wound breakdown with delayed healing, and two cases of postoperative pulmonary insufficiency, requiring intubation (one patient with aspiration at end of case, the other patient with myasthenia gravis).

Fat Grafting for Nerve Entrapment Within Burn Scars

32

CHAPTER

C. Scott Hultman and Yuen-Jong Liu

DEFINITION

- Mortality from burn injury has markedly decreased in the second half of the 20th century as wound sepsis, wound coverage, kidney failure, and shock have been largely remedied.
- Patients who have undergone tangential excision of burn injuries, escharotomies, and autografting often develop symptomatic scars.
- Superficial sensory nerves may become entrapped in burn scars and cause debilitating paresthesias, such as burning pain, tingling, or hyperesthesia.
- Although nerve decompression and neurolysis are the primary treatments for entrapment, fat grafting is a low-risk adjunct procedure that can mitigate neuropathic symptoms by capitalizing on anti-inflammatory effects and physical cushioning by autologous fat.^{1–7}
- The principles of fat grafting for burn scars may also be applied to scars from other etiologies, such as chemical exposure, frostbite, abrasion, electrical injury, or a combination of injurious energy transfer to the skin and superficial soft tissues.

ANATOMY

- Nerve entrapment may occur at any location of the body where there are sequelae of burn injury.
- Superficial sensory nerves are affected, frequently in the extremities, such as the superficial radial nerve, the medial antebrachial cutaneous nerve, the saphenous nerve, the sural nerve, and lateral dorsal cutaneous nerve.

PATHOGENESIS

- Hypertrophic scarring and contractures develop in burn scars or in split-thickness skin grafts over excised burn scars.
- The fibrotic tissues constrict around superficial sensory nerves and cause a combination of pain, hyperesthesia, and paresthesia.
- Sensory receptors in the damaged skin may also receive aberrant innervation from sensory nerves, as the integument heals.

NATURAL HISTORY

- The neuropathic symptoms are a source of frustration for the patient, often preventing return to school and work.
- They require narcotic and non-narcotic analgesics and may become tolerant.
- Adjunct analgesics include gabapentin and pregabalin, which have adverse effects of varying severity.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Complete patient history should be elicited, focusing on the type of energy delivered: scald, electrical, flame, contact, chemical, cold, friction, or abrasion.
- Previous treatments and their effects should be noted, including skin grafting, laser treatments, topical scar treatments, and medications.
- Complete physical exam should be performed, focusing on the burned area, noting whether it is a native burn scar or burn scar after skin grafting.
- Total body surface area of the burn injury should be observed, as this often dictates algorithms for treatment, that include medical therapy (compression, silicone), laser photothermolysis and ablation, nerve decompression, and fat grafting.
- Functional deficits should be noted, such as loss of range of motion or loss of sensation.
- Gentle percussion around the symptomatic area can elicit Tinel sign corresponding to the location of nerve tethering or entrapment.
- The Tinel sign can be followed to assess the effectiveness of treatment.

DIFFERENTIAL DIAGNOSIS

- Nerve compression amenable to decompression and possible transposition
- Discrete neuroma formation that may benefit from exploration, resection, and implantation of nerve below fascia or into muscle or even bone
- Persistent hyperemia of hypertrophic burn scar, which may respond to laser

resurfacing

IMAGING

- Imaging is not required, although ultrasound may be helpful in guiding diagnostic nerve blocks, to confirm diagnosis of entrapped nerve vs neuroma, and to provide temporary relief.

SURGICAL MANAGEMENT

- Fat grafting is a modality that can offer significant relief of neuropathic symptoms, after patients have been considered for or treated with laser resurfacing, nerve decompression, or neuroma resection.
- Fat grafting involves surgically controlled incisional release of the integument from the underlying subcutaneous tissues and fascia.
- The grafted fat contains adipocytes and possibly stem cells, which are thought to have anti-inflammatory effects on the entrapped nerves and scar tissue.
- The grafted volume provides mechanical padding that decreases nerve sensitivity by effectively burying afferent end fibers, deeper and away from direct contact.
- Other reasonable surgical options include scar subcision and open neurolysis.
- LipiVage is the preferred system for small volume grafting, and Puregraft is preferred for large volume, structural fat grafting.

Preoperative Planning

- Overall, fat grafting is indicated for patients with any of the following criteria:
 - Require significant pharmacologic therapy for neuropathic pain
 - Have previously undergone laser therapies for hypertrophic burn scars
 - Have multiple areas of dysesthesias not necessarily corresponding to the anatomic distribution a sensory nerve
 - Have already undergone major peripheral nerve decompression, neurolysis, and neuroma resection
- The senior author prefers to use fat grafting as “rescue” therapy for patients with chronic, neuropathic burn scar pain, who have undergone other modalities with documented success in the literature, such as laser resurfacing and peripheral nerve decompression.
- Patients with large burn scar surface areas, who are on medications for neuropathic pain, should first undergo laser treatments with pulsed dye laser to reduce hyperemia, fractional CO₂ laser resurfacing to improve pliability of

burn scar, and laser-assisted drug delivery (usually kenalog) to reduce inflammatory component.

- Patients with a discrete Tinel sign, suggestive of neuroma or entrapment, as well as those with motor dysfunction, should first undergo surgical exploration, nerve decompression, and possibly neuroma resection.
- Patients who have multiple Tinel sign, who have undergone other modalities such as laser resurfacing, and who have previously had peripheral nerve surgery, can be considered optimal candidates for fat grafting.
- Another indication for fat grafting is the patient who is on an aggressive pharmacologic regimen for chronic neuropathic pain and who wants or needs to de-escalate medications, which often lose efficacy and cause side effects of decreased level of alertness, poor sleep hygiene, and peripheral swelling.
- The role for early fat grafting, within the first 6 to 12 months after wound closure, is unknown and would benefit from prospective clinical studies.
- The role for fat grafting in prepubertal children is also not known and requires prospective clinical trials.

Positioning

- Supine, to access fat from anterior abdominal wall and lateral trunk
- Shoulders abducted at 85 degrees for upper extremity surgery, with pressure points padded
- Lower extremities prepped such that ankles, knees, and hips can be mobile

Approach

- Fat grafting is often performed in multiple sessions, as there is a limit to how much fat can be grafted into and below a burn scar, especially when there is a paucity of subcutaneous tissue present.
- The authors plan harvest and use 0.5 to 1.0 cc of fat for every cm² of surface area grafted.
- Regular liposuction or power-assisted liposuction may be used to harvest the fat.

TECHNIQUES

■ Port Creation and Cannula Use

Video p8-c032_01

- The port sites of the donor and recipient sites are first injected with a wheel of local anesthetic, typically 1% lidocaine with epinephrine, to minimize bleeding at locations.
- Donor sites ports typically include the inferior umbilicus, the flanks near the anterosuperior iliac crest, or previous surgical scars on the abdomen.
- The donor sites are tumesced with approximately 200 mL, targeting above and below the superficial fascial system using a solution of 1 L lactated Ringer's containing 1 mL of 1:100 000 epinephrine and 50 mL of 1% lidocaine.
- Tumescent is allowed to diffuse for 10 minutes.
- Port sites, of 1 to 2 mm, are made with stab incisions, proximal to the symptomatic burn scar. At least two port sites are made, to allow for a radial, fanning, cross-hatched matrix, with overlapping tunneling and at different levels in the burn scar.
- A subcision cannula is tunneled antegrade, from proximal to distal, to decrease risk of avulsing nerve branches (**TECH FIG 1**).
- Rigotomy is performed with advancement of the cannula. Usually, a blunt-tipped or semi-blunt-tipped cannula can be advanced through the scar, but occasionally, a sharp pickle-fork cannula is needed to perform discrete rigotomies.
- Fat is injected on withdrawal of the cannula, in aliquots of 0.1 to 0.2 cc, up

to 0.5 mL with the bevel up and another 0.5 mL with the bevel down, over a distance of 2 to 6 cm.

- Additional passes of the subcision cannula are repeated in a fanning fashion through each fat grafting port, centering on the focus of nerve entrapment. Care is taken to stay superficial, directly under the burn scar, to avoid disruption of the deeper afferent neural plexus.

TECH FIG 1 • A subcision cannula is tunneled anterograde, from proximal to distal, to decrease risk of avulsing nerve branches.

LipiVage

- The tubing set attached to the LipiVage Harvester is connected to an aspirator and the vacuum level is set to approximately 60% of its capacity, ensuring a gentle vacuum (**TECH FIG 2**).
- The transfer adapter is removed, and the recommended aspiration cannula is attached. The senior author prefers to use a serrated, 1 to 2 mm cannula with multiple side ports, which is helpful for extracting fat during repeat harvests.
- Fat is harvested for approximately one minute, and then fluids are drained for a few seconds, from the trap mechanism with the LipiVage system.
- The nearly bloodless lipoaspirate is then washed with normal saline, within the closed system, before processing on the back table. Fat is then transferred into 3 cc injection syringes using the transfer adapter supplied. Harvesting

steps are repeated for additional fat if needed.

- The filter is simply rinsed for a few seconds, and the plunger tip is used to wipe the inner walls of the filter clean in between harvests.
- Fat cells collect in the filter chamber suspended within the harvester body.
- Fat cells are gently pulled toward the inner walls of the filter and collect along the length of the front of the blue plunger tip, while fluids wash through.
- Once inside, the fat is gently cleaned by the accompanying tumescent fluid.
- Fluid and oils pass through the fat and the filter walls and are then carried to the waste receptacle via the tubing set.
- Due to the low vacuum levels, there is very little oil present to begin with because fewer fat cells are damaged during harvesting.
- After fluids are drained, the concentrated and cleaned fat is immediately ready for injection.
- The unique LipiVage plunger tip design gently wipes the fat from the inner filter walls and transfers the fat as the plunger is pushed forward gradually.
- The processed fat grafts are allowed to settle on the back table for at least 10 minutes, with the 3 cc syringes upside down, so that any additional tumescent fluid and oil can separate and be discarded, prior to fat grafting.

TECH FIG 2 • Attaching tubing set to the LipiVage Harvester.

■ Puregraft

Video p8-c032_02

- Fat is aspirated into a syringe.
- The lipoaspirate is injected into a Puregraft drain bag (**TECH FIG 3**).
- The lipoaspirate is washed lactated Ringer's solution.
- The filtered fat is aspirated from Puregraft drain bag into small syringes for grafting.

TECH FIG 3 • The lipoaspirate is injected into a Puregraft drain bag.

PEARLS AND PITFALLS

Port sites: harvest

- Usually, all of the lipoaspirate needed for fat grafting can be obtained through an infraumbilical incision.
- If multiple rounds of fat grafting are anticipated, we usually harvest fat from the right and left lower quadrants first, followed by the central infraumbilical fat second, and possibly the flank on repeat harvests. This is done to yield a desirable, symmetric abdominal wall contour.
- We always avoid harvesting fat from the right and left upper abdominal wall quadrants, to avoid injury to the liver or spleen, in case an aberrant pass is deflected deeper from the costal margin and into the peritoneal cavity.
- Recipient sites are closed with 4.0 plain gut and a Steri-Strip.

Port sites: recipient

- Port sites are almost always placed proximal to area of concern, so that the rigotomy can be done from proximal to distal, parallel to the topical distribution of the cutaneous nerves.
- Several port sites enable a cross-hatched matrix, which increases the amount of fat that can be transferred and should survive.
- Recipient sites are closed with 4.0 plain gut and a Steri-Strip.

Fat harvest

- We recommend against energy-assisted liposuction, such as laser or ultrasound, as this may decrease the viability of the grafted fat.
- The LipiVage system is used most of the time, as this allows for efficient harvest of the small volumes required for fat grafting. Structural fat grafting, which requires larger volumes to replace deficient tissue, is better served by the Puregraft system.

Engraftment

- For burn scars in the extremities, no tourniquet is used.
- After the cannula is advanced from proximal to distal, effecting a rigotomy, fat is injected in 0.1 to 0.2 cc aliquots, from distal to proximal.
- Pre-tunneling is not performed in order to decrease the risk of hematoma.
- We use 3 mL syringes for injecting fat during grafting, as the small size gives adequate control over delivering 0.2 mL aliquots without having to change syringes often.
- Our formula for volume of final processed and purified fat needed for grafting is 0.5 to 1.0 cc of fat for every cm² of surface area treated. Of note, we typically harvest lipoaspirate 2–3 times the

volume needed for fat grafting ultimately needed, discarding tumescent fluid and oil as these elements separate.

POSTOPERATIVE CARE

- Acute postoperative pain from donor sites and at fat grafting sites lasts no more than 2 weeks. Typically, the patient experiences more pain in the donor site than the recipient site.
- Patients are kept on their neuropathic pain regimen but do require additional narcotics, especially for the donor-site pain.
- One dose of IV antibiotics is given at induction of anesthesia, and 5 days of oral antibiotics are given in the immediate postoperative period.
- The donor site is wrapped with gentle compression for 4 weeks to minimize the risk of seroma and hematoma. For abdominal donor sites, an abdominal binder is recommended at all times except when showering.
- The patient is advised against strenuous physical activity and heavy lifting (greater than ten pounds) for 4 weeks.
- The recipient site is dressed in clean, dry, gauze to absorb any drainage from the injection ports, and the initial postoperative may be removed on the 2nd day and reapplied as needed.
- The recipient site is treated with moderate compression during early engraftment, to prevent significant edema or hematoma. We believe that similar to the principle of needing a bolster to immobilize a skin graft, during the imbibition and inosculation phases, this compression helps with engraftment of the fat, in recipient sites, which may have less than optimal vascularity. The patient is advised to avoid direct pressure on the recipient site for 4 weeks, to prevent fat liquefaction or fat necrosis.

OUTCOMES

- Fat grafting reduces neuropathic pain, in approximately 90% of patients, permitting reduction in medication regimens.
- Fat grafting reduces scar symptoms such as pruritus, hyperesthesia, paresthesia, and tethering to deep structures.
- Fat grafting can improve tendon gliding in the hand and foot.
- Fat grafting improves scar pliability, texture, and color.

COMPLICATIONS

- Complications at the donor site are essentially complications from liposuction,

which are rare, but include seroma, hematoma, and infection at the donor site.

- Complications at the recipient site have not been reported but may include infection and graft loss. Infections are exceedingly rare. In the author's practice, postoperative cellulitis occurs less than 2% of the time and can successfully be treated with oral antibiotics, continued compression, and extremity elevation.
- A small subset of patients report no improvement in neuropathic symptoms after fat grafting, but the overwhelming majority of patients report relief, measured by reduction of pain and/or reduction in need for medications. In fact, relief from neuropathic symptoms can be dramatic, suggesting that rigotomy may be the primary mechanism of early improvement. Maintenance of relief argues toward the mechanical cushioning effects of the fat graft, or possibly the ability of the adipocyte stem cells to stabilize fibrotic recipient sites or even regenerate normal afferent innervation.

Section VIII: Ear Reconstruction

Auricular Reconstruction for Microtia and Post-Traumatic Deformities

33
CHAPTER

Charles H. Thorne

DEFINITION

- Microtia literally means small ear but is used to refer to a spectrum of auricular anomalies (**FIG 1**) that are almost always associated with aural atresia (absence of the external auditory canal).
- From a practical point of view, any congenital deformity of the auricle that requires insertion of a complete or near-complete cartilage or synthetic framework is an example of microtia.
- As discussed below, the principles for reconstruction of other auricular deformities such as post-traumatic deformities are similar.

ANATOMY

- As depicted in **FIG 1**, the anomalies that constitute microtia vary from almost complete anotia to cases that demonstrate an almost normal lower 2/3 of the auricle. Microtia has been classified in various ways, but the most useful is the classification of Nagata: lobular microtia, small concha microtia, and large concha microtia. Complete anotia is almost never seen.
- Patients with microtia almost always have absence of the external auditory canal (aural atresia) with complete bony separation of the auricular remnant and the middle ear structures (**FIG 2**).

- The middle ear is underdeveloped and also presents variable abnormalities. If an apparent external auditory canal is present, it is almost always blind or stenotic. Patients with microtia, therefore, almost always have total conductive hearing loss on the affected side.
- Microtia is more common on the right side; 90% of cases are unilateral, and those patients usually have normal hearing in the contralateral ear.

FIG 1 • Variable presentation of microtia. The term microtia refers to a wide variety of presentations. **A.** Small conchal-type microtia. **B.** Lobular-type microtia. **C.** Almost complete anotia. **D.** Atypical microtia with hemifacial microsomia.

- In the 10% with bilateral involvement of microtia and aural atresia, the patients are functionally deaf and require bone conductive hearing aids on an urgent basis in order to develop speech.
- There are several anatomic differences between microtia and post-traumatic deformities:
 - The skin quality in post-traumatic cases may present problems because of scarring around the remnant.
 - Post-traumatic auricular remnants almost always contain a canal and a tragus, making reconstruction of near-normal auricle more likely.
 - Post-traumatic remnants may be distorted by scar but are almost always in the correct position, as opposed to microtic remnants that are often malpositioned.

PATHOGENESIS

- The auricle and the middle ear develop together from the first and second branchial arches, explaining the concomitant anomalies of those two structures.

- The inner ear is almost always normal in microtia patients because it arises separately in embryonic development and is not a branchial arch derivative.
- Microtia is the second most common congenital deformity affecting the head and neck (after cleft lip and palate) and is more common in patients of Southeast Asian descent.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Microtia and aural atresia fall within the larger spectrum of craniofacial microsomia or first and second branchial arch syndrome. Craniofacial microsomia can present with either unilateral (ie, hemifacial microsomia) or bilateral involvement.

FIG 2 • Aural atresia. Microtia is almost always accompanied by aural atresia. Note the absence of an external auditory canal and, in this case, an extremely hypoplastic mandibular ramus.

- Most patients with microtia have symmetrical or nearly symmetrical faces, but radiographs usually show some asymmetry of the ipsilateral mandibular condyle indicating that microtia is part of the craniofacial microsomia spectrum.
- A minority have more obvious underdevelopment of the tissues of the face including mandible, soft tissue, facial nerve, and auricle.

SURGICAL MANAGEMENT

- The autogenous method of auricular reconstruction is the technique with which this author is most familiar.¹⁻³ If the reader is interested in a technique

using synthetic frameworks, the publications of John Reinisch are recommended.⁴

- The ideal age to perform reconstruction of a missing auricle is age 10 years.
 - At this age, the contralateral ear has reached adult size, and the rib cartilages are large enough to create an adult size ear framework. In a patient who is small for his/her age, delaying surgery until the patient is approximately the size of an average 10-year-old is recommended.
- Prior to age 10, the focus of patient management is on the hearing.
 - As mentioned, a patient with unilateral microtia has a total conductive hearing loss on the affected side but normal hearing in the unaffected ear. These patients can hear normally in quiet environments, but the lack of binaural input causes difficulty with localizing sound and in discriminating sounds in noisy environments. For example, a unilateral patient will have difficulty playing football when his/her name is yelled. The patient may have trouble immediately determining the direction of the sound and may look in the incorrect direction initially. In addition, in a room with multiple voices, it is more difficult for a microtia patient to screen out the background noise to focus on a conversation. These patients benefit from a bone conduction hearing aid (**FIG 3**).
 - Patients with bilateral microtia, on the other hand, absolutely require conduction aids because they are functionally deaf and will not develop normal speech without appropriate aids.
- Hearing can be restored either surgically or by use of a bone-anchored hearing aid (BAHA).
 - Reconstruction of the external auditory canal and ossicles can be surgically performed in approximately half the cases of aural atresia. In the other 50% of cases, the anatomy is too deranged for surgical repair.

FIG 3 • BAHA soft band. Infants with unilateral microtia benefit from the BAHA soft band, which will provide binaural hearing. Patients with bilateral aural atresia must have a bone conduction aid in order to hear and to develop normal speech.

- BAHAs are so effective, however, and less prone to complications when compared to canalplasty, that they are more commonly employed than surgical reconstruction of the canal (**FIG 4**).

Preoperative Planning

- When planning the auricular reconstruction, a tracing of the contralateral ear is made (**FIG 5**) that can be sterilized for intraoperative use. From that tracing, the surgeon then makes a drawing of the framework that would be required to produce that size auricle.
- Because the skin has a certain thickness (approximately 2 mm), the framework must be at least 4 mm shorter than the desired auricle (or shorter depending on how deep in the native lobule the framework will be placed).
- In addition, each of the convexities of the auricle must be much thinner and the concavities wider than the desired thickness on the ultimate auricle because the skin will make any raised portion of the framework (such as the helical rim) much thicker.
- Once the drawing of the framework has been made, separate drawings of each component can be made.
- At the time of surgery, only two markings must be made on the affected side prior to the induction of anesthesia:

- The lowest point on the unaffected side must be transferred to the affected side so the craniocaudal position of the ear is accurate. If this is not performed, then the lobules (and earrings) will not be in symmetrical positions.
- The angle that the ear makes with the vertical: Most auricles are approximately 15 degrees off vertical and slightly less angulated than the line created by the dorsum of the nose. There is some variability, however, and the correct angle should be marked.

FIG 4 • A bone-anchored hearing aid is secured by a magnet that is attached to a titanium implant in the skull.

FIG 5 • Templates. Tracings are made from the contralateral ear and sterilized for intraoperative use.

- The remaining measurements and drawings can be made after the patient is under anesthesia.
- Because some patients with microtia have more severe forms of facial asymmetry and may have airway issues, it is important to discuss airway management with the anesthesiologist. These patients may require more sophisticated intubation techniques or even, in the case of Treacher Collins patients, tracheostomy.

TECHNIQUES

■ Stage One

Markings and Anesthesia

- Once the patient has been intubated and prepping and draping has occurred, the plastic templates that were made preoperatively are used to draw the precise location, size, and orientation of the new auricle.
- A decision is made about the skin incision, which most commonly involves either rotation of the vertically malpositioned lobule or an incision that will allow dissection of the pocket and placement of the framework without rotation of the lobule.
- If an appropriate lobule is present and rotation will result in its being in the correct position at the caudal aspect of the new auricle, rotation is performed.
 - If on the other hand, there is an inadequate lobule or one that is located such that rotation into the correct position is impossible, then an incision without lobule rotation is performed.
 - Local anesthesia with epinephrine is injected and attention is directed to the chest.

Graft Harvest

- An incision is made over the caudal aspect of the ipsilateral rib cage, and the muscles are divided to expose the rib cartilages.
- Using the sterile, plastic templates, decisions are made about which cartilages to harvest.
- If an entire framework is required, two free floating ribs are usually required for the helical rim and the antihelix.

- The synchondrosis of two ribs is needed for the base of the framework, and sufficient additional cartilage is harvested to create the tragus-antitragus piece, small additional pieces to provide stabilization and projection, and a piece to be “banked” in the chest for the second stage of the procedure.

Pocket Dissection

- The operative field then shifts back to the temporal scalp.
- The incision is planned, with or without rotation of the lobule, and the pocket is dissected for placement of the framework. Hemostasis is obtained within the pocket.
 - The dissection of the pocket is tedious but extremely important. More complications occur from soft tissue management than from management of the cartilage or an imperfect framework.
- When the pocket is created, the congenital cartilaginous remnant, which varies tremendously, is removed.
 - Care is taken not to injure the skin in the process of removing that cartilage.

Auricle Framework Construction

- On a sterile back table, the framework is assembled (**TECH FIG 1A,B**).
- The base is carved to match the template, and the details of the scapha and triangular fossa are created using sterilized gouges.
- The antihelix is attached as an onlay graft using nylon sutures on short, thin straight needles (**TECH FIG 1C**).
 - Some surgeons prefer wire sutures.
 - Creating a good framework is extremely difficult without these specialized sutures.
- The helical rim is then attached with another series of sutures of nylon or wire.
- The last piece of the main framework to be added is the tragus-antitragus piece with the intervening incisura, an important component of the aesthetically pleasing auricle (**TECH FIG 1D**).
- Additional small pieces are frequently attached to the deep surface of the framework for stabilization and projection.
 - The most important of these extends from the base to the tragus, fixing the latter in the correct position and adding to its projection. The tragus is a thin, floppy piece of cartilage, and it is important to keep it in precisely the

correct position.

Insertion of the Framework and Wound Closure

- The framework is then inserted into the pocket along with two suction drains (**TECH FIG 2**).
- The author prefers Axiom Petite Wound Drains (REF 201AT), which are silicone drains with perforations at one end and a 19G needle at the other end for insertion into the suction tubing or Vacutainer tubes.

TECH FIG 1 • Construction of the framework. **A.** The base is carved from the synchondrosis of two rib cartilages. **B.** The antihelix and crura of the triangular fossa are attached as a single additional piece. **C.** Attachment of the helical rim. **D.** The completed framework after attachment of the tragus/antitragus piece.

- The drains are then attached to wall suction, and the overlying skin is sucked

into the interstices of the framework.

- Only at this point can one decide which excess skin to excise.
- Excision of skin prior to the application of suction may result in over-resection of skin.
- The incisions are closed with interrupted nylon sutures.
- No dressing is placed.

Chest Wound Closure and Patient Transfer

- The chest incision is closed.
- Any holes in the parietal pleura are left alone without repair, and no chest tube or suctioning of the air in the pleural space is required.
- Positive pressure ventilation pushes the air out with each breath, and if a small rim of pneumothorax remains, it is of no consequence.

TECH FIG 2 • Dissection of the pocket. A. Preoperative markings. **B.** The lobule is rotated and the pocket is dissected. **C.** The pocket. **D.** After framework insertion and attachment of the drains to wall suction.

- The cartilage chips that remain after the carving of the framework are wrapped in an absorbable mesh and used to create a “rib” to replace the caudal margin of the rib cage.
- The wound is closed in layers, and the piece of cartilage mentioned above is placed in a subdermal pocket so that it can easily be found and removed at the second stage.
- The suction drains are left attached to the tubing, which is in turn attached to wall suction.
- The recovery room is informed of the patient’s imminent arrival, the suction tubing is temporarily disconnected from the wall, the patient is transported to the recovery room, and the tubing is reattached to wall suction.
 - Most wall suction units have a range for low, intermediate, and high suction.
 - The nurses are instructed to keep the suction exactly on the line that separates low from intermediate suction.

■ Stage Two

- Approximately 6 months later, the second stage is performed (**TECH FIG 3**).
- An incision is made around the posterior 180 degrees of the framework.
- The framework is elevated as far as the antihelix at the level of the temporalis fascia.
- A tunnel is created within the soft tissue, deep to the antihelix.
- The cartilage that had been left in the chest at the first stage is removed, shaped, and placed in the pocket, deep to the framework, to provide projection.
- The retroauricular skin is undermined and advanced into the sulcus.
- A full-thickness graft is taken from the inguinal crease and used to resurface

the medial surface of the elevated framework.

- Because the cartilage graft is in a soft tissue tunnel, the skin graft has an appropriate bed.
- The alternative is to cover the graft with a temporoparietal fascial flap, but the author prefers to keep that option available in case of a complication with cartilage exposure. With that in mind, the dissection of the original skin pocket and the undermining at the second stage must avoid the superficial temporal artery pedicle.

TECH FIG 3 • Second stage with elevation of the auricle. **A.** A cartilage graft that had been banked in a subdermal pocket below the original chest incision is inserted into a fascial pocket for projection of the auricle. **B.** Example after elevation. Xeroform is packed into the sulcus for 2 weeks after bolster removal.

PEARLS AND PITFALLS

Planning

- Make sure the new auricle is in the best possible location and is the correct size and at the correct angle. A beautiful ear in the wrong place is ugly. The identification of the location is much more difficult in the patients with significant facial asymmetry where compromises may have to be made. Patients with microtia,

especially those with more overt asymmetry, often have low hairlines. The management of the hairline is major topic unto itself. One choice is to excise the hair-bearing skin, either at the time of the initial operation or secondarily, and cover the framework with a temporoparietal flap and skin graft. Another choice is to place the framework under the hair-bearing skin and secondarily remove the scalp, leaving a thin layer of tissue over the framework to support the skin graft. This latter approach is tricky and requires both meticulous dissection and close postoperative observation. If the graft does not survive, the framework must be covered with vascularized tissue on an urgent basis.

Soft tissue management

- More complications arise from errors in judgment regarding soft tissue management than from poor framework construction. Although tedious, the soft tissue dissection is a priority.

Cartilage framework

- The imperfections of the framework, although hidden initially by swelling, will eventually show through the thin skin coverage. There are materials such as Styrofoam that can be used to practice the framework construction before attempting on a patient.

Exposed cartilage

- Any skin necrosis/exposed cartilage requires immediate attention and coverage with a temporoparietal flap and skin graft.

POSTOPERATIVE CARE

- The two main issues with the postoperative care are pain management and making sure that suction is applied to the drains for the 1st day or so.
- Pain from the thoracotomy is severe and requires parenteral analgesics to be administered, at least for the first night. Pain pumps with agents such as bupivacaine have not proven to be helpful.
- The drains are left attached to wall suction until the following morning. At that point the wall suction is removed and the drains are attached to red top Vacutainer tubes (or bulb suction if preferred).
- Patients are discharged on postoperative day 2 with the drains in place.
- The drains are then changed every 24 hours by the parents or caregivers, but not much fluid comes out after the 1st day, and it may be unnecessary to leave the drains after discharge.
- The patient is seen in the office on postoperative day 5 and the drains are removed.
- The sutures in the reconstructed auricle are usually left 10 to 14 days.

FIG 6 • Example of preoperative appearance (**A**) and postoperative result (**B**) after ear piercing.

OUTCOMES

- Examples of reconstruction for microtia and for post-traumatic deformities are shown in **FIGS 6** and **7**.

COMPLICATIONS

- By far the most significant and important complication is necrosis of the skin with exposure of the underlying framework (**FIG 8**).

FIG 7 • A. Post-traumatic deformity. The remnant contains a normal concha, canal, and tragus, making an aesthetically pleasing result more likely. In this case, there was no scarring around the remnant as one might find in a burn patient or a victim of a motor vehicle accident. **B.** Framework constructed to replace the missing cartilage. **C.** Postoperative result.

FIG 8 • A. The most common serious complication is necrosis of the overlying skin with impending exposure of framework. **B.** After salvage with temporoparietal flap and skin graft.

- Small areas of necrosis (5 mm or less) over concavities will heal with conservative management.
- Anything larger or any necrosis over a convexity of the framework such as the helical rim or the antihelix will not and must be treated early and aggressively.
- If the wound is left to heal and does not do so, the area will become contaminated or infected and will require a more significant debridement.
- The workhorse for closure is the temporoparietal fascial flap with a skin graft. The proximity of this tissue and its large size makes it possible to cover almost any area of necrosis.
- In patients with craniofacial microsomia who have had other surgery and may have had the superficial temporal vessels injured by a coronal incision or a free tissue transfer, the situation becomes much more difficult. The occipital fascia can be used but tends to be thicker, and the aesthetics of the reconstruction tend to suffer more from the use of this flap.
- In emergency situations, the exposed cartilage can be covered with a large scalping flap. The hair-bearing scalp is then returned to the scalp at a second stage, leaving skin-graftable tissue over the cartilage (crane principle).
- In the absence of local tissue coverage, one may also consider a free temporoparietal fascial flap harvested from the contralateral side.

CHAPTER Stahl Ear

Akira Yamada and Arun Gosain

DEFINITION

- Stahl ear was first described by Binder in 1889.¹
- Stahl ear is a congenital auricular malformation in which an abnormal third crus traverses the scapha, resulting in posterosuperior deformation of the helix.

ANATOMY

- Type 1: Obtuse bifurcation of antihelix: Superior crus of antihelix is missing, and third crus is present. Therefore, the superior and inferior crura make an obtuse angle (**FIG 1A**).
- Type 2: Trifurcation of antihelix (extra crus); this is classic Stahl ear. The third crus extends across the scapha from the antihelix (**FIG 1B**).
- Type 3: Broad superior crus, broad third crus (protruded scapha fossa) (**FIG 1C**).

PATHOGENESIS

- Etiology is unknown.
- Abnormal course of an intrinsic transverse muscle may be associated with Stahl ear.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The third crus extends from the antihelix; the superior crus may or may not be present. The lower half of the auricle is usually normal.

NONOPERATIVE MANAGEMENT

- If the patient presents before 1 month of age, nonsurgical correction of the deformity with ear molding techniques may obviate the need for surgery.

- Ear molding techniques are most effective during the 1st month of life and are unlikely to work after the 2nd month of life.

SURGICAL MANAGEMENT

- There are three major types of normal helix-lobule curve (**FIG 2**). If the patient's helix-lobule curve falls into these three normal types, surgical correction of auricular shape may be directed toward deformities other than Stahl ear, such as prominent ear.

Preoperative Planning

- The possibility of ear molding is excluded if the patient presents after age 6 weeks. Ear shape analysis (especially helix type) is performed on the patient by applying an ear template for both auricles. Photographs are taken subsequent analysis. Based on photographic analysis, the patient shown has type A helix on both the normal (**FIG 3A**) and Stahl ear sides (**FIG 3B,C**).
- Two inflection points (abrupt change of the helix curve) are identified (**FIG 3D**), and the curve between the two inflection points is almost linear (**FIG 3E**).
- These two inflection points are the important landmark for wedge skin incision during surgery.

Positioning

- Supine position with slight head turn.
- Both auricles should be prepped in the sterile field, and the contralateral ear used as a reference in unilateral correction.

Approach

- Wedge excision is the simplest and most widely reported method.² Wedge excision is best indicated for type 2 Stahl ear. For type 1, excised cartilage may be transplanted to create the superior crus.³ Other options for type 1 are to make parallel three cartilage cuts⁴ or to place Mustarde sutures to accentuate the superior crus if there is adequate cartilage elasticity (**FIG 4A–D**).
- Cartilage turnover and rotation methods have been described but have mixed outcomes when used clinically.

FIG 1 • **A.** Type 1 Stahl ear: Superior crus is missing. **B.** Type 2 Stahl ear: There are three crus (superior crus, inferior crus, and third crus). **C.** Type 3 Stahl ear: Wide third crus and protruded scapha fossa.

FIG 2 • The classification of helix-lobule curve.

FIG 3 • Preoperative assessment of Stahl ear. **A.** The normal side ear has type A helix-lobule curve. **B.** The Stahl ear side: This is type 2 Stahl ear. **C.** Type A ear template is overlapped to assess the curve of Stahl ear. **D.** Frontal view of the patient helps to identify the change of the curve (*arrows*). **E.** Overall helix-lobule curve on Stahl ear is also type A, except around the third crus. Identification of two inflection points will determine the extent and shape of wedge excision.

FIG 4 • Surgical approach for type 1 Stahl ear. **A.** Skin incision (*dotted line*) for type 1 Stahl ear. **B.** Wedge cartilage (third crus) is excised. **C.** Cartilage defect after wedge excision is closed primarily. **D.** There are three options to create the superior crus: cartilage grafting, parallel cartilage incision, or mattress sutures.

TECHNIQUES

■ Excision and Suturing

- Mark the wedge skin excision design between two inflection points (**TECH FIG 1A,B**).
- Cartilage (third crus) excision is expected to be longer than the skin wedge excision.
- Third crus excision is extended toward the antihelix, trying not to violate the antihelix (**TECH FIG 1C**).
- The cartilage is sutured together with 5-0 PDS (Ethicon Inc., Somerville, NJ). The focus is to align the curve of the helix (**TECH FIG 1D**).
- Suture the helix portion first and then move toward the antihelix (**TECH FIG 2A,B**).

TECH FIG 1 • The marking of the wedge skin excision. **A.** Anterior view. **B.** Posterior view. **C.** The marking for wedge cartilage excision. Note that cartilage excision is usually longer than the skin excision. Do not violate the antihelix. **D.** After wedge excision, the cartilage defect is closed primarily. The focus is to align the helix.

TECH FIG 2 • After aligning the cartilage of the helix, cartilage sutures are placed toward the antihelix. **A.** Anterior view. **B.** Posterior view.

■ Skin Closure

- Skin is closed in a single layer. Absorbable sutures can be used in children.
- We prefer 6-0 nylon suture for skin closure in adult patients, to be followed by suture removal in 2 weeks.

■ Bolster Sutures (TECH FIG 3)

- Bolster sutures are used to stabilize the helix and to prevent hematoma during the immediate post-op period.
- 4-0 Prolene is used to secure the bolster suture.
- Roll gauze is made with Xeroform plus Vaseline-based antibiotic ointments.
- Bolster sutures will be removed in 2 weeks. The wound is kept dry for 2 weeks.

TECH FIG 3 • Bolster sutures are in place. Tie has to be very gentle to prevent pressure injury.

PEARLS AND PITFALLS

Identify inflection points.

- This is the most important part of surgical planning. One must analyze the curve of the helix prior to surgery.

Photographic analysis

- A slight oblique photo is best to capture the shape of the helix for analysis. Analysis of the ear on a true lateral profile is less useful for planning.

Bolster sutures

- Tying very gently is the key. Even with a gentle tie, you will see tightness at the time of maximum swelling (48–72 h).
- Check underneath the bolster suture with bright LED light for pressure injuries, especially 2–3 days postoperatively.

Keep the wound dry for 2 weeks

- Avoid showering for 2 weeks postoperatively. The bolster must be kept clean to prevent infection.

POSTOPERATIVE CARE

- Periodic wound check for 2 weeks is mandatory to avoid complications.
- Keep the wound dry for 2 weeks to prevent infection. Showering may cause redness of the wound that may be difficult to differentiate from infection.

- Remove the bolster sutures in 2 weeks. During this time, periodic checks for pressure sore or tightness of the bolster sutures are important to prevent skin necrosis.

OUTCOMES

- Satisfactory outcomes are likely following the immediate wound healing process (**FIG 5**).

COMPLICATIONS

- Incomplete correction of helical deformities
- Infection
- Hematoma: Careful bolster suture helps to prevent hematoma and to stabilize the shape of the ear during the early wound healing process.

FIG 5 • Postoperative outcome.

CHAPTER Constricted Ear

Akira Yamada and Julia Corcoran

DEFINITION AND ANATOMY

- The concept of constricted ear was proposed by Tanzer.¹ The helix and scapha are hooded, and the body and crura of the antihelix are flattened in varying degrees.
- Group 1 is the mildest form of constricted ear, often called lop ear, in which only the helix is involved (**FIG 1A**).
- Group 2 is a moderate form of constricted ear that involves helix and scapha.
 - Group 2 is divided into 2A and 2B: 2A has only cartilage deficiency (**FIG 1B**); 2B has both skin and cartilage deficiencies (**FIG 1C,D**).
- Group 3 is the most severe form of cupping and is characterized by a tubular structure (**FIG 1E**).
 - Differentiation between group 3 constricted ear and microtia can be difficult.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Constricted ear is congenital, and the etiology is unknown.
- Ear height² is significantly shorter than normal.
- The helix tends to be cupped.
- The upper portion of the antitragus (superior and inferior crus) is difficult to see.
- The shape of the lower half of the auricle is likely to be normal, especially in mild to moderate constricted ear (see **FIG 1C,D**).

NONOPERATIVE MANAGEMENT

- Nonsurgical manipulation of the ear cartilage in infancy does not work for the

constricted ear due to intrinsic deficiency of skin and/or cartilage.

FIG 1 • Tanzer constricted ear classification. **A.** Group 1: Mild helix cartilage deformity without skin defect. **B.** Group 2A: Helix and scapha cartilage deformity without skin defect. **C,D.** Group 2B: Helix and scapha deformities with both cartilage and skin defects. **E.** Group 3: Most severe form of cupping; characterized by a tubular structure.

- Molding techniques in infancy may change the shape of the auricle but is unlikely to expand skin/cartilage.
- “Constricted” means there is cartilage and/or skin deficiencies that must be augmented by surgical procedures.

SURGICAL MANAGEMENT

Preoperative Planning

- Age-matched anthropometric data of ear dimension, especially vertical height, help to distinguish deviation of the patient's ear from norms (**FIG 2**).

Positioning

- Supine position with mild head turn. Both sides should be prepped, even with unilateral surgery, so that the contralateral ear can serve as a normal reference.

Approach

- If there is no skin defect and the cartilage defect is mild (Tanzer group 1), the Musgrave⁴ procedure alone is effective to correct the deformities. If there is moderate skin and cartilage defect (Tanzer group 2B), a local skin/fascia flap plus floating rib cartilage grafting⁵ is a good choice (presenting case).
- If the skin or cartilage defect is severe, microtia surgery⁶ may be indicated.
- Recommended surgical options for skin envelope augmentation, based on the severity:
 - Mild: Grotting skin flap

FIG 2 • A type A-2, 48-mm template is used to evaluate the degree of skin and cartilage defect of the upper half of the auricle of the left ear (**A**) and right ear (**B**).³

Although the left ear has more severe skin and cartilage defect, both auricles are diagnosed as Tanzer group 2B

constricted ear.

- Moderate: Park procedure (Grotting skin flap plus fascia flap)
- Severe: Nagata microtia construction
- Recommended surgical options for cartilage defects, based on the severity:
 - Mild: Musgrave procedure
 - Moderate: floating rib (Park)
 - Severe: total framework (Nagata)

TECHNIQUES

■ Markings

- The Grotting skin flap⁷ measuring approximately 1.0 to 1.5 cm in width and 3.0 to 3.5 cm in length, is designed and elevated on the posterior surface of the superior auricle to drape the skin defects of the anterior and posterior helix and scapha.
- A bilobed flap is marked: the superior flap is a fascia flap, and the inferior flap is a Grotting skin flap. The fascia flap and the Grotting flap share a common base (**TECH FIG 1A,B**).
- A portion of the superficial temporal fascia will be attached beneath the proximal 1.5 cm of the Grotting flap to increase the vascularity of the Grotting flap (**TECH FIG 1C**).
- Three small, transverse skin incisions are marked at the helical crus, at or near the otobasion superius (the point of attachment of the superior helix to the temple), and at the descending helix (**TECH FIG 1D**).

TECH FIG 1 • A,B. Design of the bilobed flaps. 1: Fascia flap. 2: Grotting skin flap. 3: Skin incision at otobasion. 4: Skin incision at crus helicus. *Dotted areas indicate shared pedicle.* **C.** The Grotting skin flap and the fascia flap are raised as a combined flap, sharing common pedicle at the base. **D.** Three small, transverse skin incisions are marked at the helical crus, at or near the otobasion superius (the point of

attachment of the superior helix to the temple), and at the descending helix.

■ Harvesting the 8th Rib Cartilage

- A 3-cm traverse skin incision is marked at the right lower costal margin (**TECH FIG 2**). After local epinephrine injection, the skin is incised.
- After identifying the fascia of the external oblique muscle, the fascia is incised transversely. The course of the external oblique muscle is examined, and the muscle fibers are split along the course of the fibers and retracted to identify the costal cartilage.
- Care is taken to identify any perforator vessels that emerge from intercostal spaces. These vessels are coagulated with bipolar cautery well above the intercostal space.
- Prior to incising the perichondrium, a small amount of local anesthetics (eg, 0.125%–0.25% bupivacaine) is injected in the intercostal space as a nerve block.
- The anterior perichondrium of the 8th rib cartilage is gently incised with a no. 15 blade in the midline, beginning at the bone-cartilage junction.
 - A 360-degree subperichondrial dissection is performed to completely dissect the cartilage from the perichondrium.
- After 8th rib cartilage is cut at the bone-cartilage junction and removed, saline irrigation of the wound is performed.
- Once homeostasis is confirmed, the perichondrium is closed with 4-0 Vicryl. The wound is then closed in layers.

TECH FIG 2 • A 3-cm transverse skin incision at lower costal margin for harvesting 8th rib cartilage.

■ Splitting the Rib Cartilage and Creating the Skin Tunnel

- The cartilage is split longitudinally into two pieces (**TECH FIG 3A,B**).
- Splitting must be precisely in the middle for simultaneous bilateral constricted ear reconstruction.
- Through the three small skin incisions described above, a skin tunnel is created above the existing helix (see **TECH FIG 1C**).
- The split cartilage is inserted into the helical tunnel through the skin incision site at or near the otobasion superius (**TECH FIG 3C**).

TECH FIG 3 • Split 8th rib cartilage for right (**A**) and left (**B**) ears is laid over a type A-2, 48-mm template.³ **C**. The split cartilage is inserted into the helical tunnel through the skin incision site at or near the otobasion superius.

■ Transpositioning the Fasciocutaneous Grotting Flap

- After helix expansion with newly inserted helical cartilage, the skin envelope defect at or near the otobasion superius will be identified (the point of attachment of the superior helix to the temple). A bilobed skin/fascia flap will be transposed to fill the defect (**TECH FIG 4A**).
- The size and location of the skin defect varies, depending on the severity and the nature of the constricted ear.
- In the example case, both skin flap and fascia flap are transposed to cover the anterior helix and scapha on the left side (**TECH FIG 4B,C**), and only skin flap is used to cover anterior helix and scapha on the right side (**TECH FIG 4D**).

TECH FIG 4 • A. A bilobed skin/fascia flap will be transposed to fill the defect. **B,C.** Both skin flap and fascia flap are transposed to cover the anterior helix and scapha on the left ear. G, Grotting skin flap; F, fascia flap plus skin graft. **D.** Immediate postoperative view of the right ear showing a Grotting skin flap (G).

■ Wound Closure and Bolster Sutures

- The skin incision is closed in a single layer.
- A small full-thickness skin graft is harvested from the back of the auricle and grafted above the fascia flap on the left side (see **TECH FIG 2**).
- Bolster sutures are used to stabilize the helix shape and to prevent hematoma during the immediate postoperative period (**TECH FIG 5**).
 - 4-0 Prolene (Ethicon, Somerville, NJ) is used to secure the bolster suture.
 - Roll gauze is made with Xeroform plus Vaseline-based antibiotic ointments.
- Bolster sutures will be removed in 2 weeks. The wound should be kept dry until removal of the bolsters.

TECH FIG 5 • Bolster sutures are used to stabilize the construction and to prevent hematoma.

PEARLS AND PITFALLS

Template ■ A sterilized ear template helps to maintain precision during surgery.

Planning ■ Preoperative planning to assess the defects of skin and cartilage is

	critical. The ear template facilitates this process.
Costal cartilage harvesting	■ Harvesting rib cartilage while leaving the perichondrium behind is safer than harvesting cartilage with perichondrium. This helps to prevent pneumothorax and to minimize chest wall deformities.
Bolster sutures	■ A very gentle tie is the key. Even with a gentle tie, one will see tightness at the time of maximum swelling (48–72 h). Check underneath the bolster suture with bright LED light for pressure sores, especially by 2 or 3 days postoperatively. ■ The authors recommend not shampooing for 2 weeks postoperatively. Keeping the bolster dressing clean and dry helps to prevent infection.

POSTOPERATIVE CARE

- Periodic wound check for 2 weeks is strongly recommended to avoid complications.
- It is recommended to keep the wound dry for 2 weeks to prevent infection. Shampoo may cause redness of the wound and make it difficult to differentiate from infection.
- The bolster sutures will be removed in 2 weeks. Until then, periodic checks for pressure sores or tightness of the bolster sutures are important to prevent skin necrosis.

OUTCOMES

- If a balanced augmentation of the skin envelope and cartilage is achieved to expand the helix, a stable outcome is likely (**FIG 3**).

FIG 3 • Left (A) and right (B) ears are shown 3 months after surgery.

COMPLICATIONS

- Incomplete correction of the helix deformities
- Infection
- Hematoma: Careful bolster suture helps to prevent hematoma and to stabilize ear shape during the early wound healing process.

CHAPTER Cryptotia

Akira Yamada and Arun K. Gosain

DEFINITION/ANATOMY

- Cryptotia is a relatively rare congenital ear deformity. The upper portion of the auricular cartilage is partially buried beneath the skin on the side of the head, hiding the upper portion of the ear. Cryptotia is often associated with helix-antihelix adhesion that results in a narrower helical arc in the upper pole. Cryptotia is also associated with upper helix deficiency that is a manifestation of constricted ear. Cryptotia is more frequent in Asian countries. In Japan, it has been reported in as many as 1 in 500 births.

PATHOGENESIS

- The cause of cryptotia is unknown. One theory is that cryptotia is the result of an anomaly of the intrinsic transverse and oblique auricular muscles.¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- The upper portion of the helix is buried underneath the skin (**FIG 1**). If one pulls the existing helix, the upper portion of the helix comes out easily. On releasing the helix, the upper helix returns to its initial position buried beneath the temporal skin.

FIG 1 • Preoperative view of cryptotia; the upper pole of the helix is buried underneath the scalp.

DIFFERENTIAL DIAGNOSIS

- Helix-antihelix adhesion
- Constricted ear
- Microtia

NONOPERATIVE MANAGEMENT

- If the patient presents before 1 month of age, nonsurgical correction of the deformity with ear molding techniques may obviate the need for surgery.²
- Ear molding techniques are most effective during the first month of life and are unlikely to work after the 2nd month of life.
- Helix-antihelix adhesion associated with cryptotia or helix deficiency associated with constricted ear is less likely to resolve with molding techniques.

SURGICAL MANAGEMENT

Preoperative Planning

- It is important to check if the cryptotia is associated with other congenital anomalies, such as helix-antihelix adhesion or constricted ear. Pure cryptotia surgery will augment the skin deficiency but will not resolve helix-antihelix adhesion or cartilage defect of the helix associated with constricted ear.
- If cryptotia is not associated with cartilage deformities, surgery can be done in early childhood. However, if cryptotia is associated with helix deformities, the authors recommend delaying surgery until at least age 4 to 6 years because of

the possible need to harvest rib cartilage.

Positioning

- Supine position with both ears prepped, including the temporal hair near the ears

TECHNIQUES

■ Marking of Z-plasty

- Z-plasty flaps are designed along the bandlike contracture above the auricle, while pulling outward away from head (**TECH FIG 1A**). The length of triangular flap depends on the degree of buried position of helix, but in this particular case, the tip of the triangular flap is located along the hairline margin (**TECH FIG 1B,C**).
- Usually, the length of Z-plasty limb is 1.5 to 2 cm³. The anterior limb of the Z (A–C) is usually placed 5 to 10 mm from the ascending margin of the helix. The posterior limb of Z-plasty (B–D) has a more obtuse angle than does the anterior limb, and the continuous extension of the skin incision is marked beyond the retroauricular sulcus (D–E). If more mobilization of the skin flap is needed, D–E can be extended further down, and a back cut may facilitate movement of the flap toward the skin deficiency behind the upper helix (**TECH FIG 2**).

TECH FIG 1 • **A.** Triangular flap is designed along the bandlike contracture above the auricle, while pulling outward from head. **B.** The tip of the triangular flap is

located along the hairline margin. **C.** If more mobilization of the skin flap is needed, the skin incision can be extended further down. A back cut may facilitate flap movement toward the skin deficiency behind the upper helix.

TECH FIG 2 • The diagram shows the basic design of the skin flaps, and the view after the wound closure. **A.** Preoperative view of cryptotia; upper helix is buried underneath the skin. **B.** The design of the skin incision is marked while buries portion of the upper helix is pulled out. **C.** AB lies along the line of traction. Point C must be located slightly anterior to the ascending margin of helix. **D.** CABD is a Z-plasty. The incision is extended further (as far as point E) in accordance with the requirement of cartilage plasty and the extent of skin advancement. 'de' curve is located posterior than intended retroauricular sulcus. **E.** Triangular skin flap 'cab' and skin flap 'bde' is raised. **F.** Upper ear cartilage is exposed with supra-perichondrial skin flap

dissection. **G.** Triangular skin flap is transposed posteriorly, and the wound is closed primarily: this maneuver eliminates the space for buried upper helix. **H.** Upper auricle is reflected anteriorly to demonstrate the completion of wound closure: Z-plasty plus advancement flap creates enough skin envelope for new helix.

■ Skin Flap Dissection and Ear Cartilage Exposure

- Dissection of the skin flap is performed just above perichondrium to see if any cartilage modification is needed. The temporal and mastoid skin is widely undermined to facilitate skin transposition so as to augment the posterior skin defect of the upper helix.

■ Skin Flap Transposition

- After skin flap preparation and careful hemostasis, the skin flaps are transposed toward the skin deficiency at the back of superior helix, filling residual defects.³

■ Wound Closure

- The skin is closed in single layer. In most cases, there is less skin tension after transposition of skin flaps to facilitate closure.

■ Bolster Sutures

- Bolster sutures (**TECH FIG 3**) are classic techniques, popularized by Tanzer more than 50 years ago. The bolster sutures have two purposes: (a) preventing hematoma formation and (b) to form an adhesion between the flap and cartilage. Nagata uses bolster sutures for almost all ear reconstruction. The key is to (a) use soft materials (eg, Xeroform gauze with additional soaking with ample Vaseline-based ointment) and (b) tie very gently to avoid any strain to the skin. The authors use 4-0 Prolene on a double-armed, SH

needle (Ethicon Inc., Somerville, NJ). Periodic check, especially 2 days post-op when the swelling is maximum, is mandatory to prevent a pressure sore underneath the bolster sutures.

TECH FIG 3 • The view after the bolster sutures are placed.

PEARLS AND PITFALLS

Timing of surgery	■ If you are unsure about helix deformities, delay the surgery until 4–6 years of age when a floating rib graft becomes an option.
Associated ear anomalies	■ Look for helix-antihelix adhesion, and helix deficiencies associated with a constricted ear.
Design of skin flaps	■ Mark the hairline before shaving so as not to obscure the margin of the hairless posterior auricular skin.
Bolster sutures	■ Tie very gently. Use soft materials for a gauze pillow such as Xeroform soaked in Vaseline-based ointment.
Skin flap dissection	■ Skin dissection should be at uniform thickness in a plane just above perichondrium.

POSTOPERATIVE CARE

- Patients/parents should be instructed to keep the wound dry for 2 weeks. Early shampoo prior to 2 weeks may cause redness of the wound. Although this may not indicate an infection, redness is confusing for both physicians and patients. If bolster sutures are used, periodic check underneath the bolster is mandatory to prevent pressure sore.

OUTCOMES

- **FIG 2** shows the immediate outcome of surgery. If surgery is performed in early childhood, it is important to explain to the family that the child/family may notice recurrent deformities of the helix later in childhood. Families should understand that a second surgery may be considered should helix deficiencies recur. Mild helix deformities can be addressed with the Musgrave procedure. For more severe helix deformities, floating rib graft (Park) may be indicated (see chapter on Constricted Ear).

FIG 2 • The view immediately after wound closure.

COMPLICATIONS

- Infection: Infection can be caused by a break in proper sterile surgical technique or dehiscence secondary to excessive tension during closure. It can also be an untoward sequela of prior hematoma evacuation. A history of atopic dermatitis (eczema) is a warning sign. The ear canal could also serve as a reservoir of bacteria, especially in swimmers. Careful preparation of hairs near the surgical site is important to prevent infection.
- Postoperative hematoma: Hematoma is heralded by the acute onset of severe,

persistent, and often unilateral pain. If there is evidence of ongoing bleeding, reoperation and exploration are mandatory. Meticulous postoperative dressing, including bolster sutures, helps to prevent hematoma.

- Skin necrosis: When raising skin flap, it is important to raise the skin flap in the same plane and thickness to avoid irregular thickness of the skin flap. Small blunt straight scissors may be better than popular curved scissors in this respect. The proper plane of elevation for prominent ear is just above the perichondrium. A thinner dissection plane may result in skin necrosis. When using bolster sutures, it is mandatory to check for possible pressure sore beneath the bolster regularly until sutures removal 2 weeks postoperatively.
- Chondritis: Chondritis is a surgical emergency, which, if left untreated, can result in permanent deformity. Therefore, prompt debridement of devitalized tissue is necessary.
- Late sequelae of helix deformities of ear: These are mainly caused by unrecognized helix-antihelix adhesion or helix deficiencies associated with cryptotia. In order to avoid these complications, it is important to recognize the associated congenital ear deformities associated with cryptotia.

CHAPTER Prominent Ear

Akira Yamada and Arun K. Gosain

DEFINITION

- Prominent ears are a common abnormality, affecting about 5% of children. When observing other people's faces, the first thing we pay attention to is the facial triangle, eye–mouth–eye. The auricle is usually not the primary area of attention. However, if the auricle is projected more than 25 mm from the head, it tends to catch the attention of human eyes as “prominent.”

ANATOMY

- The main components of the prominent ear are (1) loss of antihelical fold, (2) concha scapha angle greater than 90 degrees, and (3) conchal cartilage excess (**FIG 1**).
- Understanding ear shape anatomy, aesthetics of the ear, ear shape dimensions, and proper anatomical location of the ear is essential to achieving a natural result for the correction of prominent ear deformity.^{1,2}

PATHOGENESIS

- The most common etiology of the prominent ear is effacement of the antihelical fold. Also a deep conchal bowl (greater than 1.5 cm) frequently contributes to the overall pathogenesis. Combination of these two is very common.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Five parameters should be assessed systematically to ensure that all components of the prominent ear deformity are recognized: (1) auriculocephalic angle, (2) scapha-conchal angle, (3) relationship of the antihelix to the helix, (4) horizontal distance from the most lateral aspect of the

helix to a point perpendicular to the skull, and (5) depth of the conchal bowl.

DIFFERENTIAL DIAGNOSIS

- Constricted ear
- Stahl ear
- Microtia

FIG 1 • Preoperative view of unilateral prominent ear (Case 2).

NONOPERATIVE MANAGEMENT

- If the patient presents in infancy, preferably less than 1 month of age, ear molding techniques may be indicated. Success of ear molding progressively diminishes after the first month of life, and after age 2 months, surgery is the only reliable option to correct the prominent ear.

SURGICAL MANAGEMENT

- If the distance from the head to the top of helix at any point is over 25 mm, it is considered to be a prominent ear.
- Because the prominent ear could be the target of bullying and ridicule during school age, the most popular timing of surgery is before the start of primary school.
- There seems to be a slightly different prominent ear concept among different cultures. Generally speaking, Asian countries are more tolerant to prominent ear, because the “big ear” is a good sign of luck and wealth.

Preoperative Planning

- Preoperative anthropometric measurement of the auricle is extremely important to achieve symmetry of the projection of the auricle postoperatively. The direct measurements also help to assess the nature of prominence. For example, if the patient has more prominence in the lower pole (25 to 30 mm), it is likely that conchal hypertrophy exists. To assess the degree of projection, the authors recommend measuring at least three points (eg, upper, middle, and lower) from the head to the top of helix. An otoplasty grid provides objective data of projection from the top to the tail of the helix (**FIG 2**). In case of unilateral prominent ear, otoplasty grid taken from normal data can be used as an intraoperative template to achieve symmetry (**FIG 3**).

FIG 2 • Preoperative assessment of projection (Case 1).

Prediction of the Projection Reduction

- 20 mm distance from the mastoid to the peak of helix is acceptable projection, especially in Asian countries. In the United States, somewhere between 15 to 20 mm is the reasonable goal to achieve. The trend of ear projection in the patient's family is a good indicator for the targeted height of projection.

FIG 3 • Otoplasty grid is used to assess the postop helix-mastoid distance on the (A) left and (B) on the right.

Preoperative Quantification of Prominence by Otoplasty Grid

- After determining the goal of projection, the authors create a customized otoplasty grid for the patient, with a planned projection from the mastoid to the peak of the helix (15 mm in **FIG 2**). Upon placing the grid at the back of the auricle, one can visualize the amount of reduction needed for surgery.

Positioning

- Supine position with bilateral auricle preparation is recommended, even for the unilateral prominent ear, so as to check for symmetry (**FIGS 4** and **5**). One should also prepare the hair adjacent to the ears.

Approach

- Most cases need a combined approach to correct the deformities. Among numerous techniques reported in the literatures, Mustardé mattress sutures are the most commonly used method to create the antihelical fold.³
- Stenstrom-type anterior scoring⁴ can be applied to more rigid cartilage in older children and adults to facilitate folding of the antihelix. One must be aware that adult cartilage is also fragile, and overly aggressive scoring can cause secondary deformities with irregularity of the antihelix, which are aesthetically unfavorable.
- To prevent recurrence of the prominent ear deformity, posterior skin excision is an effective adjunct that can be combined with the Mustardé techniques (**FIG**

6). The postauricular sulcus should not be markedly decreased; thus, the amount of skin excision should be conservative. Excessive skin excision can cause tension in skin closure that may lead to hypertrophic scarring, especially in the dark-skinned population.

FIG 4 • The patient is placed in supine position to be able to assess bilateral projection.

FIG 5 • Immediate postoperative view from the front. Symmetrical set back is achieved.

- If the patient has projection over 25 mm in the lower pole, conchal hypertrophy may exist and resection of conchal cartilage and/or conchal setback may be necessary. Conchal hypertrophy can cause two unwanted effects: (i) recurrence of projection, and (ii) unnatural bending with sharp angulation of the antihelix at the level of the antitragus.

- A prominent lobule not corrected by finger pressure on the helical rim will require an additional procedure.⁵ Fishtail-type skin excision and a suture from the dermis to the scalp periosteum, identifying the point of control,⁶ are techniques to address the prominent lobule (**FIG 7**).

FIG 6 • Mustardé's radiated suture techniques are illustrated.

FIG 7 • Preoperative frontal view of Case 1 (bilateral)

prominent ears).

TECHNIQUES

■ Preoperative Marking After Intubation

- Visualizing the precise location to placing sutures: While using fingers to create ideal setback of the helix, the authors draw two curvilinear lines where the needle is planned to pass through the cartilage. Radiating direction of suture placement is also drawn (**TECH FIG 1**).

TECH FIG 1 • After intubation, curvilinear line (*red*) where sutures piercing cartilage and the direction of suture placement (*green*) are drawn on the anterior surface.

Deciding the Amount of Skin Incision

- Skin incision should be in the middle of posterior aspect of the auricle, so both helix and mastoid are accessible. The amount of skin excision should be conservative to preserve the postauricular sulcus. The skin closure should be tension free to prevent hypertrophic scarring (**TECH FIG 2**).

TECH FIG 2 • The amount of predicted skin excision is marked prior to preparation.

■ Local Injection

- 4 to 5 cc of half and half formula (mixture of 1% lidocaine with epinephrine, and 0.25% bupivacaine) is injected along the posterior skin incision, with pinpoint injection anteriorly where sutures are planned to penetrate cartilage. Injection is performed prior to skin prep to allow time for vasoconstriction.

■ Skin Flap Dissection

- The skin flap is dissected above the perichondrium. It is important to raise the skin flap in the same plane to create a skin flap of uniform thickness. The entire posterior cartilage surface can be exposed through this skin incision.

■ Identify the Two Curvilinear Lines and Draw Them on the Posterior Surface of the Auricle

- 25G needles are placed from the anterior surface through the posterior surface of the cartilage. These points are tattooed with blue ink (methylene blue). This maneuver is done for each point of insertion of the 25G needles, and the tattooed marks connected to create a curvilinear line on the posterior cartilage surface. Two curvilinear lines are drawn on the posterior surface.

■ Mattress Sutures Placement

- The authors use 4-0 double-armed needles (SH needle) for 4 points. A round needle is recommended because it is less likely to tear the cartilage. All four sutures are placed, but not tied, and held with mosquito forceps. The authors prefer to hand tie the sutures to visualize setback of the cartilage in creating the antihelix. The otoplasty grid helps to check the height of the helix from the skull (**TECH FIG 3A**). Sutures are tied sequentially from the top of the helix to the bottom. The lowest suture should be at the level of antitragus to avoid too much angulation or curve distortion of the antihelix due to the sutures. Care is taken to give a gentle curve to antihelix (**TECH FIG 3B**).

TECH FIG 3 • **A.** The view of projection immediately postoperatively on the left. **B.** The view of the anterior surface immediately after Mustardé suture placement.

■ Would Closure

- Two-layer skin closure is performed after confirmation of hemostasis and copious saline irrigation. The authors recommend lifting the helix very gently when closing the skin to minimize pull on the reshaped ear.

Bolster Sutures

- Use of bolster sutures (**TECH FIG 4**) is a classic technique popularized by Tanzer more than 50 years ago. Nagata also uses bolster sutures for most ear

reconstructions. The key is to (1) use soft materials (eg, Xeroform gauze) amply soaked in vaseline-based ointment and (2) tie very gently to avoid excess pressure on the skin. The authors use 4-0 Prolene, double-armed, SH needles for the bolster sutures. Periodic checks, especially 2 days postoperatively when the swelling is maximum, are mandatory to prevent pressure sores underneath the bolster sutures.

TECH FIG 4 • Bolster sutures are placed at the end.

PEARLS AND PITFALLS

Mustardé mattress sutures

- Try to keep the natural curve of the antihelix. Do not destroy the curve by sutures.

Two curvilinear lines

- Draw two curvilinear lines for suture placement on the posterior surface of the auricle before placing sutures.

Anterior cartilage surface scoring

- Do not abrade the cartilage too aggressively, as this may cause late cartilage deformities.

Measurement of the projection

- Check scalp-helix distance in at least three points bilaterally before and after surgery; the otoplasty grid can be used as a template.

Conchal

- If the angle of the antihelix in the vicinity of the antitragus is

hypertrophy

too acute, consider excising a small amount of concha.

FIG 8 • Preoperative posterior left side view of Case 1 (bilateral prominent ears).

POSTOPERATIVE CARE

- The authors ask patients/parents to keep the wound dry for 2 weeks. Early shampoo prior to 2 weeks may cause redness; this does not necessarily indicate infection, but it may confuse both the physician and the patient. If one uses bolster sutures, periodic check underneath the bolster is mandatory to prevent pressure sores.

OUTCOMES

- Achieving symmetry is one of the key elements for the success of prominent ear correction (Case 1: **FIGS 8–10**). Measurement of the distance from mastoid to helix is a helpful guide. The authors use the otoplasty grid to help achieve symmetry. **FIG 11** shows the outcome of unilateral prominent ear correction (Case 2), for which the otoplasty grid was used as a guide to achieve symmetry.

COMPLICATIONS

- Recurrence of prominent ear: Combined approaches instead of a single technique are better to prevent recurrence of the prominent ear. The use of resorbable sutures for the Mustardé techniques can contribute to recurrence.
- Infection: Infection can be caused by a break in proper sterile surgical

technique or dehiscence secondary to excessive tension during skin closure. Infection can also be an untoward sequela of prior hematoma evacuation. History of eczema, such as atopic dermatitis, is a warning sign. The external auditory canal could serve as a reservoir for bacteria, particularly in swimmers. Prepping the hair near the surgical site is important to prevent infection.

FIG 9 • Postoperative frontal view of Case 1 (bilateral prominent ears).

FIG 10 • Postoperative posterior view of Case 1 (bilateral prominent ears).

- Postoperative hematoma: Hematoma is a dreaded immediate postoperative complication. It is heralded by the acute onset of severe, persistent, and often unilateral pain. If there is evidence of ongoing bleeding, reoperation and

exploration are mandatory. Meticulous postoperative dressing is vital important to prevent hematoma. Compression dressings or bolster sutures are effective dressings and vary with surgeon preference.

- **Skin necrosis:** It is important to raise the skin flap in the same plane and thickness to avoid irregularity of the skin flap. Small blunt straight scissors may be better than curved scissors in this respect. The proper plane of elevation for prominent ear is just above the perichondrium. A thinner skin flap is prone to skin necrosis. When using bolster sutures, it is mandatory to check for pressure sores beneath the bolster on a regular basis until the bolster sutures are removed 2 weeks postoperatively.
- **Chondritis:** Chondritis is a surgical emergency. If left untreated, it can result in permanent deformity. Therefore, prompt debridement of devitalized tissue is necessary.
- **Dysesthesia:** Dysesthesia is an uncommon, or less recognized, complication. The best way to avoid this complication is to use a single skin incision rather than multiple skin incisions.
- **Suture granuloma and extrusion:** This is more common with permanent braided sutures.
- **Late sequelae of irregularities and deformities of the ear:** These are mainly caused by too aggressive surgical techniques to modify the ear cartilage. In order to avoid these complications, less traumatic techniques and gentle manipulation of the ear cartilages are recommended.

FIG 11 • Postoperative frontal view of Case 2 (unilateral prominent ear).

Section IX: Eyelid Reconstruction

38

CHAPTER Eyelid Coloboma

Adam R. Sweeney and Christopher B. Chambers

DEFINITION

- Eyelid coloboma (plural: colobomata) is a congenital anomaly arising from developmental interruption of the eyelid folds causing an eyelid cleft in either the upper or lower eyelid.
- The defect may be isolated and incidental but is more commonly associated with craniofacial syndromes, ocular or periocular colobomata, or other facial clefts.^{1,2}

ANATOMY

- The classic description of an eyelid coloboma is a full-thickness defect of a segment or an entire eyelid including absence of the conjunctiva, tarsus, orbicularis muscle, and skin.
- The term “pseudocoloboma” may be used to refer to a partial-thickness defect of the lid, usually involving the deeper structures with intact superficial layers.
- There is considerable variability in involvement including only a slight lid indentation to complete lid absence with underlying ocular abnormalities.
- The majority are found in the medial third of the upper lid.
- Approximately 75% of cases are unilateral.^{2,3}

PATHOGENESIS

- The etiology of eyelid colobomata is not fully understood and likely varies.
- Variability in the formation of the eyelid folds early in embryogenesis vs later disruption of eyelid fusion/fissure may implicate the location of a coloboma

defect and any associated facial clefts.^{2,4}

- Attributed etiologies include intrauterine amniotic bands, abnormalities in vitamin A metabolism, intrauterine inflammation, decreased placental circulation, hamartomas, abnormal fetal vasculature, failure of eyelid fold fusion, or abnormal fetal migration of the neural crest cells.⁵⁻⁷
- Colobomata may occur in conjunction with Goldenhar syndrome (oculoauriculovertebral dysplasia),^{1,8} Treacher Collins syndrome (mandibulofacial dysostosis),³ frontonasal dysplasia, and Delleman syndrome.⁹ Goldenhar syndrome is associated with unilateral upper lid coloboma, whereas Treacher Collins is associated with lower eyelid coloboma or pseudocoloboma.²

NATURAL HISTORY

- Untreated, an eyelid coloboma may lead to neonatal exposure keratopathy with corneal ulceration and perforation.
- A small coloboma associated with the appropriate amount of superior rotation of the eye upon eye closure, known as a Bell reflex, may be asymptomatic requiring only cosmetic surgery later in life.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Careful physical examination should be performed to assess the thickness and extent of eyelid loss in both upper and lower eyelids of both eyes. Attention should be given to the degree of skin laxity for anticipated donor lids, integrity of anchor sites on the involved lid, and skin color/thickness.¹⁰
- Fornices of eyelids should be meticulously examined for adhesions (symblepharon) that may hint at underlying diagnosis of cryptophthalmos.
- Full ophthalmic examination with cycloplegic refraction, eye motility examination, external examination, slit-lamp examination and dilated fundus examination should be performed to identify other regions of adverse development.
- Both eyes should be closely examined.
- The most common finding is an upper eyelid medial full-thickness abnormality. The defect is typically a triangular or quadrangular lesion with the base toward the eyelid margin (**FIG 1**).^{1,6,11}
- The defect may vary in severity from a small indentation to the full eyelid length.
- If present in the lower eyelid, partial-thickness defects are more common.

FIG 1 • Left upper eyelid coloboma with loss of lashes, eyelid notch, and irregular upper eyelid contour.

DIFFERENTIAL DIAGNOSIS

- Associated syndromes:
 - Goldenhar syndrome (epibulbar dermoids, preauricular appendages, blind pretragal fistulae, hemifacial atrophy, vertebral anomalies)^{1,8}
 - Treacher Collins syndrome (lower eyelash irregularities, absence of lower puncta, iris coloboma, microphthalmos, midface hypoplasia, lateral downward slant of the palpebral fissures)³
 - Delleman syndrome (orbital cysts, intracranial cysts, skin appendages)⁹
 - Other facial clefting syndromes affecting the eyelids; as described by Tessier, facial clefts
- Eyelid trauma
- Entropion
- Cryptophthalmos

NONOPERATIVE MANAGEMENT

- A small eyelid coloboma with mild corneal exposure may be treated with lubrication, bandage contact lenses, or moisture chambers with surgery deferred until 6 months of age or later when pediatric eyelid tension has

relaxed.³

SURGICAL MANAGEMENT

- Surgical correction is the preferred method of treatment.
- Surgery is required and urgently indicated in cases where exposure keratopathy is present or imminent.

Preoperative Planning

- General anesthesia is recommended for pediatric cases.
- Review the facial photos and examination including size, location, and shape of the lid defect to help determine the appropriate technique.

Positioning

- The patient is positioned supine on a surgical table with an adjustable headrest lowered to give the surgeon the best access. The patient should be prepped and draped leaving the full face exposed.

Approach

- Upper or lower eyelid lesions involving $\frac{1}{4}$ of the eyelid or less may be amenable to direct closure.
- Upper or lower eyelid lesions involving a quarter to half the eyelid are treated with Tenzel semicircular flap.
- Large lesions with significant tissue loss involving $\frac{1}{2}$ or more of the eyelid may be managed via a one-stage graft technique involving a tarsomarginal graft from the ipsilateral lower intact lid or from the contralateral intact upper eyelid.¹²
- For lesions with greater than $\frac{1}{2}$ eyelid tissue loss and not amenable to a one-stage closure, a two-stage lower lid rotation to the upper lid via a Cutler-Beard technique may be employed.¹³
- The vast majority of large colobomata involving greater than $\frac{1}{2}$ of the eyelid involve the upper eyelid; thus, techniques specifically addressing upper eyelid repair are described below. One-stage and two-stage grafting for lower eyelid closures are routinely performed and described for other conditions; however, these are out of the scope of this chapter.

TECHNIQUES

■ Direct Closure

- Place topical tetracaine on the conjunctival surface.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space around the lesion and the lateral canthus.
- Unscroll the underlying tissue of the eyelid margin to explore the full depth of the defect.

TECH FIG 1 • A,B. Upper eyelid coloboma with position of proposed canthotomy outlined in the *dotted line*.

- Using a no. 15 blade, trim the borders of the defect to prepare for a full-thickness, aligned graft site.
- Pull the defect edges together; if there is significant tension, consider a canthotomy and cantholysis (**TECH FIG 1**).
- Create a horizontal incision along the lid crease or intended lid crease from the border of the medial defect laterally along the lid crease. The extent of the lid crease incision should be lengthened to create the amount of laxity needed to approximate the lateral border of the defect to the medial border of the

defect without tension.

- Using a 6-0 Vicryl suture, make a single pass at the eyelid margin from tarsus to tarsus spanning the defect. Ensure equal depth (2 mm deep to the margin) and horizontal distance from the defect (2 mm from the defect border) to create a perfectly reapproximated closure. Apply tension to the ends of the suture to assess the alignment of the closure, but do not tie a knot.
- Using 6-0 Vicryl suture, reapproximate the deep tarsus using a buried interrupted pass. This pass should be repeated for every 2 mm of vertical tarsus absent. Do not tie the knot.
- Using another 6-0 Vicryl suture, reapproximate the eyelash line using a single pass.
- Using another 6-0 Vicryl suture, make a third eyelid margin pass reapproximating the gray line (**TECH FIG 2A**). Ensure attention is paid to the same techniques as used to reapproximate the tarsus at the margin.
- Tighten all the sutures. The eyelid margin should realign with a slight eversion. If the eyelid has perfect reapproximation, tie all the knots with a 3-1-1 knot. Leave the suture tails 3 to 5 mm long (**TECH FIG 2B**).
- Close the superficial skin using 7-0 fast gut interrupted sutures. Tie the knots of the sutures with the tails of the Vicryl suture under the knot to keep the eyelid margin suture tails from rubbing against the cornea (**TECH FIG 2C**).
- Close the relaxation incision with 7-0 fast gut sutures in an interrupted fashion.
- Apply erythromycin ointment over the wound.

TECH FIG 2 • Margin involving defect closure. **A.** Simple closure of a small eyelid defect including three eyelid margin passes: one through the tarsus, one through the gray line, and one through the lash line. **B.** Deep nonmarginal tarsus passes are closed first in buried fashion. Tying of margin involving knots is then performed leaving suture tails 3 to 5 cm long. **C.** Close the superficial skin incorporating the marginal suture tails in the skin closure knots to detract the tails from the cornea.

■ Tenzel Semicircular Flap

- Place topical tetracaine on the conjunctival surface.
- Using a sterile marking pen, draw a semicircle at the lateral canthus

inferiorly oriented for upper lid repair or superiorly oriented for lower lid repair (**TECH FIG 3A**).

- Inject 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space around the defect extending to the frontozygomatic suture.
- Unscroll the underlying tissue of the eyelid margin to explore the full depth of the defect.
- Using a no. 15 blade, incise the skin and orbicularis tissue along the marked semicircle beginning at the lateral canthus.
- Undermine the musculocutaneous semicircular flap laterally using blunt dissection to create lid laxity (**TECH FIG 3B**).
- Complete a full-thickness canthotomy using Westcott scissors.

TECH FIG 3 • A,B. Diagram depicting inferiorly oriented semicircular orientation for large upper lid coloboma repair.

- Grasp the lateral aspect of the involved eyelid and gently apply anterior traction to expose the canthal tendon. For an upper eyelid coloboma, perform a superior arm cantholysis; and for lower eyelid coloboma, perform an inferior arm cantholysis (**TECH FIG 4A,B**).
- The cantholysis of the respective arm of the canthal tendon is performed by strumming the multiple attachments of the respective arm with closed scissors and then cutting each attachment, ensuring further laxity is felt with each cut (**TECH FIG 4B**). Avoid cutting conjunctiva by maintaining adequate visualization and hemostasis with handheld cautery.
- Full cantholysis is achieved when the respective eyelid can be distracted to reach the superior orbital rim for an inferior cantholysis or the inferior orbital rim for a superior cantholysis (**TECH FIG 4C**).

- Using a no. 15 blade, trim the borders of the defect to prepare a full-thickness, aligned graft site. This should be attempted to create a rectangle-shaped border to ensure easier closure.

TECH FIG 4 • Lateral canthotomy and cantholysis. A. Following canthotomy, a lateral cantholysis is performed by grasping the eyelid margin and brought anteriorly to expose the multiple canthal tendon arms. For upper lid repairs, a superior cantholysis is performed; for lower lid repairs, an inferior cantholysis is performed (**B**). **C.** Full lower lid cantholysis is achieved when the lower lid can be distracted superiorly to the superior orbital rim. Similarly, an upper lid cantholysis is achieved when the upper lid can be distracted to the inferior orbital rim.

- Using forceps, distract the loose eyelid margin to bring together the edges of the wound (**TECH FIG 5A**). Mark the temporal aspect of the distracted eyelid that aligns with the lateral canthus of the uninvolved/unaffected eyelid.

- Close the eyelid defect wound using the steps described in the “direct closure” technique above (**TECH FIG 3**).
- Using a single interrupted 5-0 Vicryl suture, make a pass through the deep tissues along the repaired eyelid where previously marked at the intended site of lateral canthus reconstitution. Secure this suture by passing it through the periosteum of the underlying lateral orbital rim exiting 1 to 2 mm superior to the entrance of the pass (**TECH FIG 5B**).
- Secure the lateral aspect of the flap using 5-0 Vicryl suture by making a single pass through the deep tissues of the flap, into the underlying prezygomatic fascia, and then out the deep tissue of the opposite side of the flap to create a buried suture adherent to the underlying fascia.
- Repeat this step with interrupted sutures to fully close the length of the flap.
- Reconstitute the lateral canthus by suturing the upper lid gray line to the lower lid gray line approximately 2 mm from the termination of the lateral gray line using 6-0 Vicryl suture.
- Close the superficial skin of the flap using 7-0 fast gut suture in an interrupted fashion.
- Apply erythromycin ointment over the wound.

TECH FIG 5 • A. Align the tissue with minimal tension to the lateral canthus of the opposite eyelid. **B.** Secure the tissue with a 5.0 vicryl suture through the obicularis muscle to the orbital rim periosteum.

■ One-Stage Graft (Tarsomarginal Graft)

- Place topical tetracaine on the conjunctival surface.
- Using a sterile marking pen, draw an inferiorly oriented semicircle at the

lateral canthus.

- Inject 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space around the defect and the contralateral upper eyelid.
- Unscroll the underlying tissue of the eyelid margin to explore the full depth of the defect.
- Using a no. 15 blade, trim the borders of the defect for a full-thickness, aligned graft site.
- Using calipers, measure the dimensions of the missing underlying tarsus.
- Mark the contralateral (donor) upper eyelid with the calipers per the dimensions measured for the graft upper lid using an inferior border that is superior to the eyelid margin (**TECH FIG 6**).

TECH FIG 6 • Scheme depicting one-stage contralateral upper eyelid graft using donor conjunctival/tarsus to host eyelid. Host upper eyelid anterior lamella is placed over the graft after undermining superiorly and laterally.

- On the contralateral (donor) upper eyelid, use Westcott scissors to dissect a plane at the level of the orbicularis oculi, extending to the marked borders between the posterior lamella (conjunctiva and tarsus) and the anterior lamella (orbicularis muscle and skin).
- Using Westcott scissors, amputate the graft of tarsus and conjunctiva from the contralateral donor upper eyelid within the borders marked, sparing the eyelid margin.
- Bring the tarsomarginal graft into the donor site and suture the grafted tarsus to the host tarsus with two interrupted 6-0 Vicryl sutures per side leaving the eyelid margin free of suture. Ensure the knots are buried deep, avoiding potential conjunctival or corneal abrasion from posterior oriented knots.

- Using Westcott scissors, reconstruct the donor upper lid anterior lamella by undermining deep to the patient's adjacent orbicularis muscle using Westcott scissors. Advance the adjacent anterior lamella over the graft tissue ensuring no vertical tension is created. Close this tissue with interrupted 7-0 gut passes.
 - Close the posterior lamella of the donor eyelid via the "direct closure" of deep horizontal eyelid lesion technique described above (**TECH FIG 3**).
 - Apply erythromycin ointment over both eyelids.
-

■ Two-Stage Graft (Cutler-Beard)

- Place topical tetracaine on the conjunctival surface.
- Inject 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space of the upper and lower eyelids.
- Unscroll the underlying tissue of the eyelid margin to explore the full depth of the defect.
- Using a no. 15 blade, trim the borders of the defect for a full-thickness, aligned graft site. This should be attempted to create a rectangle-shaped border to ensure easier closure.
- Using a sterile marking pen, make two vertical markings on the lower lid to outline the borders of the horizontal defect of the upper lid. Connect the vertical markings of the lower lid horizontal mark placed 4 mm inferior to the eyelid margin.
- Pass a 4-0 silk traction suture into the lower eyelid margin ensuring a tarsal bite is achieved.
- Using a no. 15 blade, incise the skin and orbicularis over the horizontal marking (**TECH FIG 7A**).
- Holding the silk suture by the tails, evert the lower lid over an eyelid retractor and make a horizontal conjunctival incision. This incision should be deep to the horizontal marking previously placed on the lower eyelid skin.
- Using Westcott scissors, incise through the conjunctival incision full thickness to connect to the anterior lamella incision.
- Using Westcott scissors, make deep orbicularis cuts through the vertical markings of the lower lid (**TECH FIG 7B**).
- With toothed forceps, grasp the superior edge of the flap created by the full-thickness horizontal incision already created. Bring this flap under the lower

eyelid margin (through the blepharotomy) and place it into the region of the upper eyelid defect (**TECH FIG 7C**).

- Suture the lower lid grafted tarsus to the tarsus at the borders of the upper lid coloboma using 5-0 Vicryl suture with at least two passes per side ensuring anteriorly oriented knots to avoid conjunctival abrasion (**TECH FIG 7D**).
- Undermine around the lid defect until the anterior lamella is lax enough to close the anterior lamella directly and without tension using 5-0 Vicryl sutures (**TECH FIG 7E**).
- Close the superficial skin of the flap using 7-0 fast gut interrupted passes.
- Apply erythromycin ointment over the wound.
- The second stage is performed by releasing the flap with Westcott scissors at the intended eyelid margin. Excess conjunctiva and skin can be removed from the upper eyelid (**TECH FIG 8**).

TECH FIG 7 • First stage of Cutler-Beard procedure. **A.** Incision is made through skin and orbicularis over the horizontal marking. **B.** Incision through the vertical markings is made revealing full tarsoconjunctival flap. This is dissected from the anterior lamellae. **C.** The flap is grasped and sutured into the graft position allowing laxity of tissue. **D.** The graft is sutured into position using 5-0 Vicryl suture ensuring anteriorly oriented knots. **E.** The anterior lamellae host tissue is

then sutured into position using 7-0 fast gut.

TECH FIG 8 • Second stage of Cutler-Beard procedure. **A.** Incise the graft tissue at the desired upper lid margin using a metal backing to protect the underlying cornea. **B.** Marginal and graft are then sutured ensuring no knots exposed to the cornea.

- The remaining conjunctiva is sutured into place to the anterior edge of the eyelid margin using 7-0 fast gut sutures with the knot placed away from the cornea (**TECH FIG 9**).
- In children between birth and 14 years old, the second stage is performed at 2 weeks, rather than the recommended 4 to 6 weeks, to minimize the risk of deprivation amblyopia.

TECH FIG 9 • Suture the excess conjunctiva over the anterior edge of the eyelid margin with a fast gut suture.

PEARLS AND PITFALLS

Choosing a technique

- Two-stage repairs for large colobomata incur a period of visual deprivation that can lead to amblyopia. Full consideration of one-stage technique, when applicable, is recommended.
- Skin laxity and eyelid graft development must be considered when choosing a graft. There is tendency to underestimate the tension and required modifications to adequately close pediatric eyelid defects.

Timing of surgery

- Children less than 3–6 months of age have less skin laxity, and when not contraindicated, postponement of surgery may achieve better outcomes. When early surgery is indicated, the lateral canthotomy and cantholysis described in the “direct closure” technique offers improved eyelid relaxation, decreasing horizontal tension.

POSTOPERATIVE CARE

- Prescribe topical application of antibiotic ointment over the wounds 3 times a

day for 1 to 2 weeks.

- Recommend sun tan lotion to improve scar results.
- Comanagement with pediatric ophthalmologist is recommended for regular refraction and monitoring for development of primary or secondary strabismus or corneal scarring.

OUTCOMES

- Surgical success is dependent on the degree of the coloboma and the procedure type selected.
- Irregular postoperative eyelid contour may occur if the lid defect is closed under too much tension.³

COMPLICATIONS

- Exposure keratopathy from unintended vertical traction
- Loss of lashes from the graft or trichiasis
- Entropion or ectropion
- Ptosis secondary to poor levator function or postoperative horizontal traction
- Poor appearance

CHAPTER Congenital Ptosis

Adam R. Sweeney and Christopher B. Chambers

DEFINITION

- Blepharoptosis, commonly referred to as ptosis, is eyelid positioning inferior to normal posture. Often, ptosis is defined as asymmetry of 1 mm or more between the two upper eyelids or a marginal reflex distance of less than 2.5 mm.¹
- Congenital ptosis refers to cases presenting within the first year of life, as an isolated finding or as a manifestation of ophthalmic or systemic disorders.
- Typically, congenital ptosis results from fibrofatty degeneration of the levator complex.
- Congenital ptosis affects an estimated 1 in 842 births in the United States.¹

ANATOMY

- The anterior lamella is made up of the skin and the preseptal orbicularis (**FIG 1**).
- The posterior lamella is made up of the tarsus and the palpebral conjunctiva.
- The tarsus is a fibrous plate located in the eyelid. It is 9 to 10 mm in height in the upper eyelid and 4 mm in height in the lower lid. The length of the tarsus is approximately 22 to 25 mm.
- Posterior to the orbital septum lies the preaponeurotic fat pad, an important surgical landmark.
- The levator aponeurosis is the primary retractor of the upper eyelid and is located just posterior to the preaponeurotic fat.
- The levator palpebrae originates above the annulus of Zinn and attaches to Whitnall ligament, a transverse facial suspensory structure. This attachment allows the levator muscle's horizontal vector to be redirected to the vertical

vector created from its anterior extension, the levator aponeurosis, which terminates at the anterior tarsus.

- Muller muscle arises from the posterior layer of the levator muscle and inserts into the upper border of the tarsal plate.
- The lid crease is formed from levator aponeurosis fibers inserting into the fascicular bundles of the pretarsal orbicularis.
- In patients not of Asian descent, the lid crease is located between the upper border of the tarsus and the insertion of the orbital septum, which is approximately 3 to 5 mm superior to the upper border of the tarsus. The lid crease is approximately 9 to 11 mm and 8 to 9 mm superior to the eyelid margin in females and males, respectively.
- In Asians, the lid crease is much lower secondary to a more anterior preaponeurotic fat pad and low/absent attachment of the aponeurosis fibers to the fascicular bundles of the pretarsal orbicularis.

FIG 1 • Anatomy of the upper eyelid.

- The levator muscle is a striated muscle and is innervated by cranial nerve (CN) III, whereas Muller muscle is a smooth muscle innervated by the sympathetic chain.
- The frontalis muscle inserts into the orbicularis oculi at the inferior brow.

PATHOGENESIS

- There are multiple different etiologies of congenital ptosis.

- Approximately 80% of congenital ptosis arises from dysgenesis or fibrosis of the levator muscle with remaining integrity of the levator aponeurosis, termed myogenic ptosis or simple congenital ptosis.^{1,2}
- Myogenic ptosis is more common unilaterally than bilaterally.
- Neurogenic etiologies are much less common and arise from innervation abnormalities during development such as abnormal motor nerve connections of the levator muscle and branches of the trigeminal nerve innervating the external pterygoid muscle (Marcus Gunn jaw winking), interrupted sympathetic nervous chain (Horner syndrome), congenital cranial nerve III palsy, or congenital cranial dysinnervation disorders such as Duane retraction syndrome.
- Aponeurotic ptosis is caused by a defect in the tendon's ability to redirect the action supplied by the levator muscle. This is classically different from disinsertion of the aponeurosis from the levator muscle, as is commonly seen in advancing age or from trauma including childbirth.
- Mechanical ptosis is caused by a forced inferior excursion of the eyelid such as seen in tumor, eyelid inflammation/edema, cicatricial processes, or foreign body.
- Traumatic ptosis usually can be found to be inclusive in one of the above categories and may arise in utero or from trauma, such as during childbirth.

NATURAL HISTORY

- Congenital ptosis may be mild and benign with no impact on vision or function of the child.
- Severe congenital ptosis may cause amblyopia due to deprivation or astigmatism.
- Twenty to thirty percent with congenital ptosis have concurrent strabismus or astigmatism.^{3,4}
- Twenty-five percent of patients with congenital ptosis develop amblyopia of the involved eye.²

PATIENT HISTORY AND PHYSICAL FINDINGS

- Hallmark findings distinguishing congenital myogenic ptosis from acquired ptosis: absence or irregular upper eyelid crease, decreased levator function (particularly prominent in upward gaze), eyelid retraction in downward gaze, and presence of lagophthalmos (a common finding in congenital ptosis).
- Marcus Gunn jaw-winking ptosis involves elevations of the eyelid with

pterygoid muscle movement usually evident with sucking or chewing. Monitoring for association of lid height in various gazes and facial movements including jaw movement is important to rule out this condition.

- Horner syndrome classically manifests with ptosis, meiosis, and anhidrosis ipsilateral to the neurological defect. Ipsilateral lower lid inverse ptosis may also be seen. Heterochromia characterizes the congenital form from acquired Horner syndrome and necessitates systemic workup.
- Margin reflex distance (MRD) of the upper lid and vertical palpebral fissure height should be routinely assessed, when possible.
- MRD₁ in down gaze, evaluating chin, head, and brow position should be noted as compensatory mechanisms.
- Strength of Bell phenomenon (eye elevation and abduction on attempted lid closure) may indicate whether dysgenesis of the levator muscle includes the superior rectus muscle.
- Perform a pupil exam monitoring for symmetry.
- Test extraocular muscle movements assessing for partial CN III palsy or assessing for hypotropia-related pseudoptosis.
- Test the frontalis contribution by immobilizing the brow in primary position as children often will attempt to correct ptosis by recruiting the frontalis muscle.
- Assess corneal exposure issues with fluorescein staining.
- The phenylephrine test is performed by instilling one eye drop of 2.5% phenylephrine to the inferior cul-de-sac. This elevates the eyelids within 10 minutes via the sympathetic response on smooth muscles of the eyelid, principally Muller muscle. The MRD₁ should be assessed before and 10 minutes after instillation. Demonstration of adequate improvement of the ptosis after phenylephrine test may guide the surgical technique required, such as a Muller muscle resection. Unilateral phenylephrine dosing may reveal a contralateral ptosis masked by Hering law of equal bilateral innervation.
- Attaining visual acuity and fixation preferences may help detect amblyopia. Evaluation of these patients with a pediatric ophthalmologist is important.

IMAGING

- Quality full facial photographs should be obtained for preoperative planning and intraoperative reference.
- In older children or adults with congenital ptosis, visual field testing with taped and untaped eyelids should be performed.

- An A-scan may be performed if one is concerned about pseudoptosis, a term describing ptosislike appearance from pathology independent of the eyelid, such as microphthalmia or advanced hyperopia.
- Cycloplegic refraction or autorefraction may be performed to detect ptosis-induced astigmatism that may be amblyogenic.
- Congenital Horner syndrome should be evaluated with a tumor workup that may necessitate MRI investigation.

DIFFERENTIAL DIAGNOSIS

- Myogenic: myasthenia gravis, chronic progressive external ophthalmoplegia, muscular dystrophy, and oculopharyngeal dystrophy
- Myogenic etiology also seen in blepharophimosis-ptosis-epicanthus inversus syndrome (BPES), which also may have euryblepharon, telecanthus, ear deformities, and hypoplasia of the superior orbital rims and nasal bridge
- Neurogenic: Marcus Gunn jaw-winking ptosis, Horner syndrome, aberrant regeneration of the oculomotor nerve, Duane retraction syndrome
- Aponeurotic ptosis refers to slowly progressive ptosis from involutional changes in the levator aponeurosis with gradual stretching or dehiscence of this structure.
- Mechanical ptosis from excessive upper eyelid weight such as secondary to an eyelid mass, foreign body, or eyelid edema
- Pseudoptosis: Microphthalmia (underdevelopment of the orbit, lids, and socket) or advanced hyperopia with smaller anteroposterior globe length

NONOPERATIVE MANAGEMENT

- If ptosis is not cosmetically bothersome and does not appear to affect visual axis or lead to astigmatism, observation may be appropriate.

SURGICAL MANAGEMENT

- When potentially amblyogenic, prompt ptosis surgery is indicated.
- The timing of surgical correction in the absence of visually threatening ptosis is debated with many advocating for correction at approximately age 4 when structures are more defined and the child is more cooperative⁵; however, others suggest earlier treatment advocating ease of development and postoperative care.
- Consideration of the type of surgery should reflect the degree of ptosis, levator function, and emphasis on cosmetic outcomes.

- Surgeon preference often is considered when choosing a technique; however, surgeons should be comfortable with the major techniques including frontalis suspension, levator resection, and Muller muscle surgery.
- When levator function is less than 3 to 4 mm, frontalis suspension is typically preferred when possible.^{2,5}
- External levator resection or advancement may be employed for patients with moderate levator function and mild to moderate ptosis.^{2,5}
- A poor Bell phenomenon may require a temporary lower lid retraction suture, or Frost suture, to protect the cornea following ptosis surgery.
- Frontalis suspension may utilize a silicone, Mersilene mesh, Gore-Tex, Ptose-Up strips, or Supramid material. However, if the child is older than 3 or 4 years, autogenous fascia lata may be utilized, which some report yields better results.⁶

Preoperative Planning

- General anesthesia is recommended for pediatric cases.
- Review of the facial photos and exam including attention to the MRD₁, vertical fissure height, Bell phenomenon, and extraocular muscle
- For levator resection surgeries, the degree of levator function should be reviewed preoperatively. Unlike adult cases with intraoperative participation, pediatric cases under general anesthesia may require a preplanned amount of resection or intraoperative lid position. Berke offered guidelines for leaving the upper eyelid level 1 to 2 mm below the limbus if levator function is greater than 8 mm, at the limbus for levator function of 8 mm, and 1 to 2 mm above the limbus if levator function is less than 8 mm.⁷
- We recommend unilateral frontalis suspensions for unilateral congenital ptosis; however, some recommend bilateral surgery with extirpation of a functional levator muscle to offer improved symmetry.

Positioning

- Patient is positioned supine on a surgical table with an adjustable headrest lowered to give the surgeon the best access. The patient should be prepped and draped by leaving the full face exposed.

Approach

- Internal (posterior) approach: mullerectomy

- External (anterior) approach: levator resection
- Frontal approach: frontalis suspension

TECHNIQUES

■ Frontalis Suspension

Markings and Eyelid Sutures

- Place topical tetracaine on the conjunctival surface.
- Mark the lid crease prior to injecting local anesthetic.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine subcutaneously inferior to the brow.
- Mark desired lid crease with a sterile marking pen. This is typically 8 and 10 mm above the eyelid margin in males and females, respectively.
- Mark one midpupillary point on the eyelid skin. Mark two points 4 mm medial and lateral to the marked “central point” superior to the brow (**TECH FIG 1A**).
- Make one stab incision at each of the marked stab sites above the brow with a no. 15 blade.
- Make an incision with a no. 15 blade along the previously marked eyelid crease.
- Attach a free needle to the sling material. The authors prefer Supramid (polyfilament, cable-type 3-0 suture). Pass this needle laterally to medially along the eyelid crease beneath the orbicularis muscle and just anterior to the tarsus (**TECH FIG 1B**). If the skin puckers while doing this, the needle is being passed too superficially.
- Check the eyelid contour to ensure the tarsus pass does not create squared off lid (too broad of a pass) or a peaked eyelid (too narrow of a pass).
- Both medial and lateral ends of the sling material are then passed just deep to the dermis to the stab incision sites immediately superior to the brow (**TECH FIG 1C**).
- Close the eyelid crease incision with 6-0 fast gut running sutures (**TECH FIG 1D**).

Brow Sutures

- Pass the needle from the lateral brow stab incision to the medial stab incision deep to the dermis (**TECH FIG 2A**).
- Tighten the sling material with care not to break the sling elevating the lid to the height of the superior limbus or 1 mm below the superior limbus. Assess eyelid contour.
- If using synthetic material, pass a cuff around both sling ends (**TECH FIG 2B**).
- Secure the sling with two square knots.
- Close the stab incisions with a deep pass using 5-0 Vicryl suture on a P-2 needle and finally closing the eyelid crease and superficial tissues of the stab incisions with 5-0 fast gut interrupted sutures (**TECH FIG 2C,D**).

TECH FIG 1 • Frontalis sling. **A.** Markings are made, importantly including one midpupillary point on the eyelid skin and two points 4 mm medial and lateral to the marked midpupillary point superior to the brow. **B.** A free needle attached to the sling material of choice is passed laterally to medially beneath the orbicularis and anterior to the tarsus. **C.** Both medial and lateral

ends of the sling material are passed just deep to the dermis to the stab incision sites superior to the brow.
D. The eyelid crease incision is closed in running fashion.

TECH FIG 2 • Frontalis sling. **A.** The sling needle is passed from the lateral brow stab incision to the medial stab incision deep to the dermis. **B.** Demonstration of passing a cuff around both ends of a silicone sling to be buried subcutaneously. **C.** Deep 5-0 Vicryl suture is placed underneath the sling prior to tying the sling. The Vicryl suture is then passed through subcutaneous tissue anterior to the enclosed sling. **D.** The stab incisions are closed with a deep pass using 5-0 Vicryl suture on a P-2 needle.

■ Levator Resection

Markings and Dissection

- Place topical tetracaine on the conjunctival surface.
- Mark the desired lid crease (8 to 10 mm) with a sterile marking pen aligning symmetry with the fellow eye.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space adjacent and superior to the tarsus. Take care not to infiltrate the levator muscle with local anesthetic or add too much volume to the lids, distorting surgical landmarks.
- Use a no. 15 blade to incise the marked eyelid crease deepening the incision with scissors to the level of the tarsus (**TECH FIG 3A**).
- Using Westcott scissors, make short cuts along the inferior edge of the incision to dissect to the superior tarsus (**TECH FIG 3B,C**).
- Tent up the eyelid septum by holding and gently retracting the tarsus and the superior septum away from each other. Carefully cut shallowly to dissect through the septal plane revealing the levator aponeurosis (**TECH FIG 3D**).

Suturing and Closure

- Pass 2 double-armed 5-0 Vicryl sutures through the anterior upper tarsus border via partial-thickness passes (**TECH FIG 3E**). Take care to avoid making full-thickness passes, checking the palpebral conjunctiva for suture by flipping the eyelid after each pass (**TECH FIG 3F**).

TECH FIG 3 • Levator resection. **A.** An incision is made along the marked eyelid crease and deepened with Westcott scissors to the level of the tarsus. **B.** Careful sharp dissection is made to dissect to the superior tarsus. **C.** The tarsus is seen by glistening white tissue (*arrow*). **D.** The tarsus and superior septum are retracted to allow a dissection through this pocket to the levator aponeurosis (*arrow*). **E.** Two double-armed 5-0 Vicryl sutures are passed through the anterior upper tarsus border via partial-thickness passes. **F.** The eyelid is flipped using a blunt needle driver to ensure full-thickness passes have been avoided. **G.** Sutures are passed through the levator aponeurosis to the junction of Whitnall ligament, demarcated by a white linear band (*white dashes*). **H.** A temporary knot is tied, and the contour of the eyelid is checked. **I.** Excess levator aponeurosis (between *black brackets*) can be excised. **J.** The skin is closed

in running fashion.

- Per the graded resection anticipated prior to the procedure, each suture is then passed through the levator aponeurosis, near the junction of Whitnall ligament (**TECH FIG 3G**).
- A temporary knot is tied and the contour of the eyelid is checked (**TECH FIG 3H**). If appropriate lid height is achieved, the sutures can be permanently tied using a surgeon's knot.
- Excess levator aponeurosis (**TECH FIG 3I**) can be excised if needed.
- Close the skin with 6-0 fast gut in running fashion (**TECH FIG 3J**).
- If interested in recreating the eyelid crease, make a single pass of 6-0 gut suture through the inferior edge of skin, orbicularis, passing partial thickness through the levator aponeurosis, and exiting via the superior orbicularis and skin. This effectively attaches it to the levator aponeurosis to recreate the skin crease.

■ Conjunctivomullerectomy

- Place topical tetracaine on the conjunctival surface.
- Place a subcutaneous eyelid block below the brow using 2 cc 2% lidocaine with 1:100 000 epinephrine. Evert the eyelid and inject 1 cc lidocaine into the superior tarsal border deep to the conjunctiva (**TECH FIG 4A**).
- Pass a 4-0 silk suture deeply through the gray line to serve as traction sutures (**TECH FIG 4B**).
- Evert the eyelid using a Desmarres retractor.
- Using a caliper, measure the amount of Muller muscle to resect and mark inside the lateral borders of the tarsus with handheld cautery (**TECH FIG 4C**).
- Pass a two 4-0 silk sutures through the conjunctiva and Muller muscle at the marked sites (**TECH FIG 4D**).
- Elevate Muller muscle and the conjunctiva via the silk sutures into a mullerectomy clamp at the marked sites (**TECH FIG 4E**).
- Lock the clamp. Cut and remove the silk traction sutures from the Muller muscle.
- Hold the clamp in the nondominant hand between the middle and index finger leaving the thumb and index finger to load suture.

- Holding this position, run a 6-0 double-armed Vicryl suture in running horizontal mattress fashion along the entire end of the locked clamp. Repeat the running horizontal mattress passes with the second suture arm (**TECH FIG 4F**).
- Tie the two Vicryl suture arms with a surgeon's knot.
- With slight upward tension, use a no. 15 blade to incise the tissue held by the clamp with attention to incising as close to the metal clamp edge as possible keeping a metal-on-metal feel to ensure the suture is not cut (**TECH FIG 4G**).
- Remove the mullerectomy clamp and retraction sutures (**TECH FIG 4H**).

TECH FIG 4 • Conjunctivomullerectomy. **A.** Anesthetic is injected into the superior tarsal border deep to the conjunctiva. **B.** A 4-0 silk suture is passed deeply

through the gray line to serve as traction sutures. **C.** The predetermined amount of Muller muscle to resect is measured with calipers inside the lateral borders of the tarsus and marked with handheld cautery. **D.** Two 4-0 silk sutures are passed through conjunctiva and Muller muscle at the marked sites. **E.** Grasping the sutures, Muller muscle and the conjunctiva are elevated into a mullerectomy clamp at the marked sites. **F.** Running horizontal mattress sutures passed below the clamp. **G.** Incision of Muller muscle and conjunctiva held in the clamp ensuring sutures are not cut. **H.** Final appearance after removal of clamp.

PEARLS AND PITFALLS

Creating an eyelid crease

- Gently push superiorly on the upper eyelid lashes. This will manifest an eyelid crease that may be otherwise underrepresented.
- If a natural eyelid crease is not present and is surgically desired, create a crease with an incision 8–10 mm superior to the upper eyelid margin for males and 10–12 mm for females.

Undercorrection

- Utilize the results from the phenylephrine test to plan for the degree of expected correction for mullerectomy procedures.
- Adjustable sutures may be used for early postoperative adjustment.
- Err on the side of undercorrection, unless performing levator resection, in which case aim for 1 mm overcorrection.

Irregular eyelid contour

- Avoid closing or removing levator aponeurosis with the mullerectomy by grasping conjunctiva with Muller muscle from the more posterior structures.
- Place or adjust sutures where the deformity is greatest after applying tension under this region.

	■ Postoperatively, lid massage may be of benefit in mild to moderate cases.
Ectropion/entropion	■ Avoid suture tension at the inferior tarsus. ■ Avoid applying too much tension to sutures.
Postoperative lagophthalmos	■ Consider graded mullerectomy and tarsectomy in patients with significant preoperative lagophthalmos. ■ If frontal sling is needed in a setting of significant preoperative lagophthalmos, place a temporal tarsorrhaphy at the end of the procedure. ■ Place Frost sutures after levator resection procedures.

POSTOPERATIVE CARE

- Patients undergoing frontalis sling should be given an oral antibiotic for 7 days.
- Coordinate care with pediatric ophthalmologist to monitor for postoperative refractive error including induced amblyopia.
- Aggressive lubrication cannot be overstressed.
- If used, lower lid traction sutures should be removed at postoperative day 2.
- Topical antibiotic ointment should be applied 4 times a day for 1 week.
- If adjustable sutures are employed, the postoperative visit should be within 1 week.

OUTCOMES

- Overall, the reported successful outcome is 70% to 90% in pediatric ptosis cases with undercorrection accounting for the majority of poor results or failures.^{2,8}
- Frontalis sling procedures using synthetic material historically have had recurrence rates as high as 29% to 40%; however, autogenous fascia lata grafts and newer graft materials used in a sling procedure may offer superior results.^{5,6,9} Lee et al.² reported 5% to 10% poor outcomes with fascia lata grafts or Mersilene mesh.
- Anterior levator resection procedures result in poor outcomes in approximately 10% to 20%.^{2,7}
- Although not generally agreed upon, some surgeons find external levator resection to be associated with less reoperation rate.¹⁰
- An asymmetry of greater than 1 to 2 mm between eyelids may be as common

as 30% postoperatively.⁸

COMPLICATIONS

- Lagophthalmos
- Overcorrection
- Ectropion
- Exposure keratopathy
- Irregular eyelid contour or skin crease
- Implant infection or extrusion⁶
- Development or worsening of astigmatism postoperatively⁴
- Suture site granulomas over synthetic material

CHAPTER Epiblepharon

Adam R. Sweeney and Christopher B. Chambers

DEFINITION

- Epiblepharon is a congenital eyelid anomaly in which inward rotation of the normal lash line toward the globe results in eyelash approximation to the cornea and/or conjunctiva.

ANATOMY

- A horizontal eyelid fold composed of skin and orbicularis is evident inferior to the eyelid margin. This is caused by the absence of the adhesion between the thin smooth muscle contributing to lower eyelid retraction and the soft tissue immediately deep to the lower eyelid skin.^{1,2}
- Often, the fold is more pronounced or isolated to the medial eyelid.
- The Asian lower eyelid has a higher attachment of the septum on the tarsus or inferior retractor. Additionally, there often is an absence or paucity of retractor septa attached to the overlying skin, similar to the Asian upper eyelid.¹
- The tarsus is not rolled in, nor is there rotation of the eyelid muscle, separating this condition from entropion.³

PATHOGENESIS

- Epiblepharon is one of the most common eyelid abnormalities among Asian children, with majority demonstrating spontaneous resolution throughout childhood.⁴
- Up to 95% of Asian children with epiblepharon will have it bilaterally.^{2,4,5}
- Epiblepharon much more commonly involves the lower eyelid than it does both upper and lower eyelids with a small minority of cases involving solely the upper eyelid.²

- There is no gender predilection.²
- Epiblepharon is less commonly seen in adults.
- Asian children with higher BMI are more likely to have epiblepharon.⁶
- Acquired epiblepharon is rare and often secondary to thyroid eye disease.⁷

NATURAL HISTORY

- The majority of patients will have spontaneous resolution with growth of the midface stretching and flattening the redundant fold.
- Patients with untreated epiblepharon may have a continuum of sequelae with some asymptomatic until development of thicker eyelashes, whereas others may develop conjunctival epithelial defects, corneal defects, recurrent corneal infections, and even corneal scarring.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients may be asymptomatic or have inciting surface irritation evident by rubbing of eyes, photophobia, persistent tearing, or discharge.
- Eyelashes may be vertically oriented and may touch the cornea. This often is exacerbated in down gaze.
- Fluorescein staining may reveal epithelial defects.
- Epiblepharon may be associated with astigmatism.
- Diagnosis is by physical exam with the eyelashes directed vertically in the setting of normal eyelid position (**FIG 1**). Additionally, an eyelid fold may be found to be mechanically corrected with downward pressure applied on the skin away from the eyelid involved.

IMAGING

- Preoperative quality external photos documenting resolution of the epiblepharon with eyelid fold excursion are recommended prior to undergoing surgery.

DIFFERENTIAL DIAGNOSIS

- Entropion with or without epiblepharon
- Trichiasis, or misdirected growth of eyelashes toward the eye
- Epicanthus tarsalis
- Dermatochalasis with lash ptosis
- Ptosis
- Discharge in nonverbal children may be a sign of backflow from the tear

drainage pathway, caused by nasolacrimal duct obstruction.

FIG 1 • Lower lid epiblepharon. Eyelashes are seen directed vertically with inferior eyelid fold.

NONOPERATIVE MANAGEMENT

- Monitoring is appropriate in asymptomatic cases without corneal eyelash apposition.
- Lubrication with scheduled artificial tears may suffice in asymptomatic cases with mild epiblepharon or conjunctival eyelash apposition.

SURGICAL MANAGEMENT

Preoperative Planning

- General anesthesia is recommended for pediatric cases.
- Surgical intervention is warranted in children whose lid abnormality causes keratopathy or conjunctivopathy, considerable irritation, or in cases where lubrication is not tolerated.
- Goals of surgical management are to achieve eyelid retractor tightening, removal of a strip of orbicularis and skin, and creation of a scar in a region between the preseptal and pretarsal orbicularis.
- In patients for whom a surgical eyelid crease is not desired, the standard

technique for epiblepharon is used. If a surgical eyelid crease is desired, the modified Hotz technique is used.

- A noninvasive everting suture technique may be offered. This modality may be appropriate for mild cases of epiblepharon, parents wishing to avoid creation of an eyelid crease/scar, or avoidance of general anesthesia.

Positioning

- The patient is positioned supine on a surgical table with an adjustable headrest lowered to give the surgeon the best access. The patient should be prepped and draped, leaving the full face exposed.

Approach

- An external approach to the lower lid tarsus and eyelid retractors is classically used. Alternatively, a noninvasive suture technique may also be used.

TECHNIQUES

■ Standard Technique

Markings and Incisions

- Place topical tetracaine on the conjunctival surface.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space adjacent to the eyelid margin of the lid involved.
- Using a sterile marking pen, outline the deficit nasally and temporally with a horizontal mark placed along the nonmarginal tarsus border (**TECH FIG 1A**).
- Use calipers to ensure the measured strip does not exceed 2 to 2.5 mm vertically (**TECH FIG 1B**).
- Use a no. 15 blade to incise a vertical semilunar-shaped strip of orbicularis and skin (**TECH FIG 1C**).
- Remove the incised skin using Westcott scissors (**TECH FIG 1D**).

TECH FIG 1 • **A.** Epiblepharon with outlining markings including a horizontal marking along the nonmarginal tarsus border. **B.** Calipers are used to confirm less than 2 mm of vertical tissue to be excised. **C.** The outlining incision is made. **D.** Westcott scissors are used to excise outlined skin.

Suturing

- Maintain hemostasis with monopolar cautery.
- Remove the incised orbicularis using handheld cautery (**TECH FIG 2A**).
- Using a 5-0 Vicryl suture, make a pass through the orbital septum and through the lower eyelid retractors (**TECH FIG 2B**).
- Continue this pass through the inferior edge of the tarsus, rotating the needle to pass out through the septum (**TECH FIG 2C**).
- Rotate the eyelid to ensure a full-thickness eyelid suture has not been placed and tie this knot using a surgeon's knot (**TECH FIG 2D**).

- Pass two identical sutures separated by approximately 2 to 3 mm closing the horizontal length of the strip (**TECH FIG 2E-G**).
- Using 5-0 Vicryl suture, close the superior and inferior edges of the incised orbicularis tissue in buried subcutaneous-interrupted passes.
- Close the skin with 6-0 fast gut running sutures (**TECH FIG 2H**).

A

B

C

D

E

F

G

H

TECH FIG 2 • A. Handheld cautery is used to remove underlying orbicularis within the previously marked region. **B.** Vicryl suture is passed through the orbital septum and lower eyelid retractors. **C.** The pass is continued through the inferior edge of the tarsus. **D.** A surgeon's knot is used to reapproximate the sutured tissues. **E.** The retractors are reapproximated to the tarsus. **F.** Suture tails are cut just above the knot. **G.** Eyelashes are checked for resolution of corneal apposition. **H.** Skin is closed using 6-0 fast gut in a running fashion.

■ Modified Hotz Technique

Markings and Incisions

- Place topical tetracaine on the conjunctival surface.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space adjacent to the eyelid margin of the lid involved (**TECH FIG 3A**).
- Using a sterile marking pen, outline the eyelid crease prior to marking the epiblepharon deficit nasally and temporally with a horizontal mark placed along the nonmarginal tarsus border.
- Use a no. 15 blade to incise a 2- to 2.5-mm vertical semilunar-shaped strip of orbicularis and skin (**TECH FIG 3B**).
- Remove the incised skin using Westcott scissors (**TECH FIG 3C**).
- Maintain hemostasis with monopolar cautery.
- Remove the incised orbicularis using handheld cautery (**TECH FIG 3D**).

Suturing

- Using a 5-0 Vicryl suture, pass the needle externally through the skin inferior to the incision, through the orbital septum, and through the lower eyelid retractors (**TECH FIG 4A**).
- Proceed by passing this needle through the inferior edge of the tarsus (**TECH FIG 4B**), rotating the needle to pass out through the septum, the

orbicularis, and the skin superior to the incision (**TECH FIG 4C**).

- Rotate the eyelid to ensure a full-thickness eyelid suture has not been placed.
- The suture can then be tied with an external surgeon's knot.
- Pass one identical suture both nasal and lateral to the central suture 2 mm from the nasal and lateral tarsal edge, respectively (**TECH FIG 4D**).

TECH FIG 3 • **A.** Anesthetic is injected into the subcutaneous space along the defect. **B.** The outlining incision is made. **C.** Westcott scissors are used to excise outlined skin. **D.** Handheld cautery is used to remove underlying orbicularis within the previously marked region.

TECH FIG 4 • A. 5-0 Vicryl suture is passed externally through the skin, through the orbital septum, and through the lower eyelid retractors. **B.** The pass is continued through the inferior edge of the tarsus and out through the skin. **C.** Eyelashes are checked for resolution of corneal apposition. **D.** The final outcome and appearance of the surgically created lid crease.

TECH FIG 5 • Illustration outlining the trajectory of the suture through the central cul-de-sac of the palpebral conjunctiva directed superiorly to exit 3 mm below the eyelid margin.

■ Everting Sutures/Buried Sutures Technique

- Place topical tetracaine on the conjunctival surface.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine into the subcutaneous space adjacent to the eyelid margin of the lid involved.
- Using a double-armed 3-0 silk suture, make a pass from the central cul-de-sac through the palpebral conjunctiva, orbicularis, and the eyelid skin (**TECH FIG 5**).
- The ideal exit of this suture is 3 mm below the eyelid margin for inferior epiblepharon repair and 3 to 4 mm above the eyelid margin for superior

epiblepharon repair.^{8,9}

- An identical suture is passed 2 to 3 mm medial to the central suture in the same fashion.
- The sutures are tied with long tails and the tails.
- Antibiotic ointment is applied over the suture site.
- The tails of the sutures are taped away from the eyelid margin.

PEARLS AND PITFALLS

Technique	■ In very large epiblepharon cases, a modified Z-epicanthoplasty to tighten the lower eyelid to the medial canthus may be performed prior to the standard or modified Hotz procedure. ¹⁰
Inadequate postoperative eversion	■ Overcorrect the eversion slightly to adjust for postoperative scarring.
Asymmetry	■ More orbicularis/skin may be taken medially to avoid recurrence and asymmetry.
Scar	■ Avoid tension on the skin. ■ Lubricate and protect the incision site from sun exposure postoperatively.

POSTOPERATIVE CARE

- Apply antibiotic eye ointment to the operative site 4 times a day for 1 week.
- Remove everting nonabsorbable sutures at 1-week follow-up, allowing for orbicularis scarring.

OUTCOMES

- Following incisional epiblepharon repair, 80% to 90% of patients are either asymptomatic or anatomically repaired.^{2,5}
- The everting sutures/buried sutures technique may be associated with up to a 23% recurrence rate.⁹
- There is no agreed-upon interval between surgical correction and possible recurrence.

COMPLICATIONS

- Suture abscesses
- Wound dehiscence
- Lid retraction, ectropion
- Canalicular trauma
- Lagophthalmos

CHAPTER Canthopexy

Adam R. Sweeney and Christopher B. Chambers

DEFINITION

- Canthopexy is a resuspension of the canthus to the bony orbit used to treat eyelid laxity, ectropion, or misalignment.
- A common surgery in adult facial rejuvenation, canthopexy is an indispensable tool for treating children with eyelid positioning defects or deformities.

ANATOMY

- The canthal tendons maintain the shape of the palpebral fissure and also maintain lid apposition to the globe, important for proper corneal lubrication and tear drainage.
- The medial canthus has origins at the anterior and posterior lacrimal crests that *fuse temporal* to the lacrimal sac, enveloping the lacrimal sac. The medial canthus then divides into upper and lower segments that attach to the tarsus of the upper and lower lid.
- The medial canthus is involved in the lacrimal pump mechanism and intimately associated with the lacrimal sac.
- The lateral canthal tendon originates at the lateral orbital tubercle 4 to 5 mm posterior to the lateral orbital rim. This provides a posterior vector opposing the lid to the globe. The lateral canthal tendon then splits into superior and inferior segments that attach to the tarsal plates (**FIG 1**).
- The lateral canthal tendon inserts approximately 2 mm higher than does the medial canthal tendon. This creates a superior tilt to the palpebral fissure moving laterally.
- The orbital septum overlies the lateral canthus as it approaches the orbital rim and acts as a “superficial lateral canthus,” which can be used for suspension in

mild cosmetic defects.¹

PATHOGENESIS

- Common conditions that may cause eyelid laxity or malposition including congenital facial clefting (ie, Tessier 2 to 12 clefts), amniotic band syndrome, congenital eyelid malposition, or deformities resulting from other etiologies including trauma and cancer resection or from craniofacial manipulation (iatrogenic)

NATURAL HISTORY

- Eyelid laxity is both a cosmetic and a functional problem.
- Uncorrected, lower lid laxity may cause exposure keratopathy, epiphora, or problems with the lacrimal pump mechanism.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Lower eyelid laxity
- Canthal dystopia

FIG 1 • Anatomy of the medial and lateral canthal tendons.

- Poor eyelid snap back test: This test refers to evaluating the time for the eyelid to return to normal position after pulling the lower lid down and away from the globe. It is graded from 0 (brisk snap back) to IV (severe laxity).

- Eyelid distraction—5 mm of eyelid distraction often considered excessively lax.
- Dry eye including exposure keratopathy or punctate epithelial erosions
 - Punctual stenosis from keratinization of the lid margin in medial ectropion²

IMAGING

- CT imaging of the face is appropriate in the evaluation of congenital craniofacial abnormalities. In the setting of orbital trauma, CT imaging is useful to assess for naso-orbital-ethmoid fractures.

NONOPERATIVE MANAGEMENT

- In patients not bothered by the cosmetic defect, scheduled application of lubricant artificial tears may provide the necessary corneal protection to defer or prevent surgery in mild cases.
- Careful attention must be made to prevent deprivation amblyopia by constant application of ointments, taping the eyelid shut, or patching of the eye.

SURGICAL MANAGEMENT

- If the cosmetic defect is bothersome or the patient is symptomatic, canthopexy, canthoplasty, or both may be performed to correct the eyelid abnormality.
- Medial canthopexy in the absence of nasal fractures may be performed either with or without wiring as adapted from Mustarde³ and Callahan,⁴ respectively.

Preoperative Planning

- General anesthesia is recommended for pediatric cases.
- Preoperative photos should be reviewed assessing the degree of malpositioning and marking of the face at the desired canthi position to create the proper slight superolateral contour of the eyelid with appropriate eyelid tightening achieved.

Positioning

- Patients should be positioned supine in an operating bed with adjustable head positioning. The contralateral eyelid may be temporarily taped shut or lubricated rather than covered to serve as a reference point during surgery.

Approach

- Medial, lateral, or a combination of approaches may be performed depending on the location of the lid abnormality or the desired results.

TECHNIQUES

■ Lateral Canthopexy

- The lateral canthopexy procedure tightens the canthal tendon with sutured reconstruction of the canthal tendon. This effectively tightens the eyelid.
- Place 2 drops of topical tetracaine on the conjunctival surface.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine subcutaneously above and below the lateral canthus.
- Using a no. 15 blade, make a 1-cm horizontal subciliary incision at the lateral canthal angle (**TECH FIG 1A**).
- Retract the skin with skin hooks and bluntly dissect down to the periosteum using blunt-tipped scissors.
- Undermine and dissect in this plane to the lateral canthal tendon under the orbital septum (**TECH FIG 1B**).
- The lateral canthal tendon is identified by tension and the ability to “strum” if manipulated by closed blunt-tipped scissors. Grasping the lateral canthal tendon, vertically transect the lateral canthal tendon at its lateral insertion taking care to avoid the levator aponeurosis (**TECH FIG 1C**).
- Pass a double-armed 4-0 Vicryl suture on a P-2 needle (Ethicon, Somerville, NJ) entering anteriorly through the lateral canthus at its transected superior and inferior attachment points (**TECH FIG 1D**).

TECH FIG 1 • Lateral canthopexy. **A.** A 1-cm horizontal subciliary incision is made at the lateral canthal angle. **B.** Blunt-tipped scissors are used to dissect down to the periosteum. **C.** The lateral canthal tendon is grasped following undermining to assist in further dissection. **D.** A double-armed 4-0 Vicryl suture on a P-2 needle is used to make two passes from anterior to posterior through the lateral canthal tendon. **E.** Deep suture placement ensuring a bite of periosteum is achieved at the (medial) aspect of the lateral orbital rim. **F.** The eyelid laxity in the operative eye (*arrow*) is assessed for appropriate tension.

- Pass each suture through the periosteum of the inner (medial) aspect of the lateral orbital rim approximately 1 cm superior to the medial canthus (**TECH FIG 1E**). Ensure tension is achieved with a strong bite.
- Check the tension of the eyelid to ensure slightly exaggerated tension, anticipating slight laxity after postoperative healing (**TECH FIG 1F**).

- Close with 2 deep passes to approximate soft tissues including the periosteum and orbicularis using 4-0 Vicryl suture.
- Close the skin with 6-0 fast gut suture.

■ Lateral Canthoplasty (Lateral Tarsal Strip)

- The terms lateral canthoplasty and lateral tarsal strip are interchangeable. This procedure involves reconstruction of the lateral canthal tendon with lysis and reattachment of the tendon.
- Place 2 drops of topical tetracaine on the conjunctival surface.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine subcutaneously above and below the lateral canthus.
- Using a no. 15 blade, make a 2-cm partial-thickness skin incision at the lateral canthus (**TECH FIG 2A**).
- Use Westcott scissors to make a full-thickness cut at the site of the prior incision.
- Disinsert the inferior arm of the lateral canthus from the periosteum at the lateral incision site using Westcott scissors, strumming the canthal attachment points with closed scissors to find remaining canthal tendon arms that need to be released (**TECH FIG 2B**).
- The lower eyelid should be freely mobile to the superior orbital rim once all canthal attachments have been cut.
- Grasping the lateral tarsus at the lateral most point with toothed forceps, use Westcott scissors to separate the anterior and posterior lamellae (**TECH FIG 2C,D**).

Creating the Lateral Tarsal Strip

- Remove the mucocutaneous junction prior along the length of the desired lateral tarsal strip (**TECH FIG 3A**).
- Using Westcott scissors, cut the grasped tissue inferior to the inferior border of the tarsus, 5 mm inferior to the lid margin (**TECH FIG 3B**).
- De-epithelialize the skin and conjunctiva off the strip using a scraping technique with a no. 15 blade (**TECH FIG 3C**).

TECH FIG 2 • Lateral tarsal strip (lateral canthoplasty). **A.** Lateral canthotomy is performed. **B.** Cantholysis is performed using Westcott scissors. There may be multiple arms of the tendon that need to be cut. **C,D.** Westcott scissors are used to separate the anterior and posterior lamellae.

TECH FIG 3 • Lateral tarsal strip (lateral canthoplasty).

A. The mucocutaneous junction is removed from the eyelid margin. **B.** Grasping the lateral canthus, the lateral tarsal strip is fashioned by cutting the inferior border of the tarsus 5 mm inferior to the lid margin. **C.** An ideal strip is created by de-epithelializing the skin and conjunctiva off the strip using a scraping technique with a no. 15 blade. **D.** Both arms of a double-armed suture are passed from posterior to anterior through the lateral end of the tarsal strip.

- Pass both arms of a double-armed 4-0 Vicryl suture on a P-2 needle from posterior to anterior through the lateral end of the tarsal strip, with one arm passing superiorly and one arm passing inferiorly (**TECH FIG 3D**).
- Pull the inferior lateral canthus superiorly into the desired position, generally 1 cm superior to the medial canthus.

Suturing

- Secure both arms of the suture by passing the needles deeply into the medial

periosteum of the lateral orbital rim (**TECH FIG 4A**).

- Check the tension of the eyelid to ensure slightly exaggerated tension, anticipating slight laxity after postoperative healing (**TECH FIG 4B**).
- Using 6-0 fast gut suture, reform the lateral canthal angle with a circular stitch entering from the inferolateral wound, out the gray line of the lower lid, through the gray line of the upper lid, and out the superolateral wound (**TECH FIG 4C**).
- Close the skin using 6-0 fast gut suture.

TECH FIG 4 • Lateral tarsal strip (lateral canthoplasty).

A. Both arms of the suture are secured deeply in the medial aspect of the lateral orbital rim periosteum. **B.** Tension of the eyelid is checked. **C.** The lateral canthal angle is reformed with a circular stitch entering from the inferolateral wound, out the *gray line* of the lower lid, through the *gray line* of the upper lid, and out the superolateral wound.

■ Y-V Medial Canthopexy

- Place 2 drops of topical tetracaine on the conjunctival surface.
- Inject 1 to 2 cc 2% lidocaine with 1:100 000 epinephrine subcutaneously above and below the medial canthus.
- With a sterile marking pen, draw a horizontal V terminating 5 mm medial to the medial canthal angle. Extend the marking with a 3-mm line horizontally from the tip of the V (**TECH FIG 5A**).
- Incise the skin and orbicularis using a no. 15 blade over the markings.
- Using Westcott scissors, bluntly dissect through the orbicularis and septum to the depth of the medial canthus ensuring to stay anterior to the nasolacrimal system (**TECH FIG 5B**).
- Pass both arms of a 4-0 double-armed silk suture underneath the lateral aspect of the medial canthus exiting anteriorly through the medial canthus. With each suture arm, make an additional pass through the medial canthus extending medially. Pull the suture arms to plicate the medial canthus (**TECH FIG 5C**).
- Tie the two suture arms with a surgeon's knot.
- Close the soft tissues using 6-0 Vicryl sutures in interrupted fashion and close the skin with 6-0 fast gut suture (**TECH FIG 5D**).

TECH FIG 5 • Y-V medial canthopexy. **A.** Markings of the V-Y with the point of the V terminating 5 mm medial to the medial canthal angle with a 3-mm horizontal extending line that is parallel to the palpebral fissure. **B.** Blunt dissection to the level of the medial canthus. **C.** Plication of the medial canthus with two throws of a double-armed suture extending medially. **D.** Soft tissue and overlying skin closed separately in interrupted fashion.

Technique	■ In children expected to have multiple facial surgeries, avoid a large amount of canthal tendon resection as this may render further procedures on these structures more difficult.
Inadequate postoperative suspension	■ Overcorrect the anatomic lateral canthopexy position slightly aiming for 1 cm superior to the medial canthus to allow for postsurgical laxity. ■ In procedures requiring a pass through periosteum, ensure the periosteum has indeed been grasped by applying a moderate amount of anterior tension on the suture after the pass. The tension felt on the suture should be firm. ■ When making a pass through the periosteum, aim to create a posterior vector to ensure the eyelid is approximated to the globes laterally.
Scar	■ Avoid tension on the skin. ■ Push on the inferior eyelashes to exaggerate the subciliary fold for accuracy of marking.

POSTOPERATIVE CARE

- If used, nonabsorbable sutures should be removed at 5 to 7 days postoperatively.
- Apply antibiotic eye ointment to the operative site until the suture absorbs.
- Sunscreen and lotion should be liberally applied over the operative region.

OUTCOMES

- Lateral canthoplasty is associated with an 83% reduction in discomfort by subjective grading scales and near universal improvement in objective eyelid position.⁵

COMPLICATIONS

- Improper positioning of fixation arm
- Loosening of the canthus
- Persistent pain lasting up to 3 months
- Eyelid contour abnormalities including rounding of the canthus
- Chemosis
- Eyelid imbrication can be seen if the inferior crus of the lateral canthal tendon is preferentially tightened or positioned too far cephalad.
- Epithelial inclusion cysts may occur in the lateral tarsal strip procedure if the tarsus is not denuded of epithelium prior to insertion.

Nasolacrimal Duct Obstruction

CHAPTER

Emily M. Zepeda, Sarah M. Jacobs, and Christopher B. Chambers

DEFINITION

- Nasolacrimal duct obstruction (NLDO) is an obstruction that occurs within the duct of the nasolacrimal system, such that tears and mucus that have passed through the lacrimal sac are unable to appropriately drain into the nose.
- NLDO results in varying degrees of epiphora (tearing) and is often associated with mucopurulent discharge, swelling, and pain.

ANATOMY (LACRIMAL SYSTEM)

- The nasolacrimal duct is a part of the lacrimal drainage system that conveys tears from the ocular surface to drain into the nose (**FIG 1**).
- It is about 15 mm long, starting at the terminus of the nasolacrimal sac.
- The nasolacrimal duct passes inferiorly, posteriorly, and laterally within the canal formed by the maxillary and lacrimal bones. It travels into the inferior meatus and opens under the inferior turbinate. Its outflow is partially covered by the valve of Hasner.

FIG 1 • Anatomy of the nasolacrimal system, which allows tears from the eye to pass through the puncta, canaliculi, and lacrimal sac, through the nasolacrimal duct to drain into the nasal cavity.

PATHOGENESIS

- NLDO can occur secondary to congenital or acquired disease.
- Congenital NLDO is usually secondary to a membrane blocking the valve of Hasner at the nasal end of the NLD.
- Obstructions become clinically evident in only 2% to 6% of full-term infants at 3 to 4 weeks of age.
- Conservative management options of congenital NLDO consist of observation, lacrimal sac massage, and topical/oral antibiotics. It is estimated that 90% of symptomatic congenital NLDO resolves in the first year of life with conservative management.

- For the remaining 10% of these cases, probing of the NLD can be curative by creating an opening through the imperforate valve of Hasner.¹
- Infants with craniofacial deformity or Down syndrome are also at higher risk of congenital NLDO. Dacryocystoceles can also create an obstructive process, leading to enlargement and potentially abscess of the lacrimal sac.
- Acquired NLDO may arise from numerous causes such as facial trauma, sinus disease, chronic allergy and inflammation, radiation treatment to the midface, toxicity from chemotherapeutic agents or radioactive iodine, or following sinonasal surgery. Involutional stenosis is the most common cause of NLDO in adults.
- Regardless of whether NLDO is congenital or acquired, any obstruction of the nasolacrimal outflow is capable of causing stagnation of bacteria leading to infection of the lacrimal sac known as dacryocystitis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- In both congenital and acquired NLDO, the primary symptom is epiphora as a result of backflow of tears due to blockage of the duct.
 - At times, enough tear and mucous volume is accumulated within the lacrimal sac that there is a palpable or visible enlargement of the sac. Light pressure over the area of the lacrimal sac can often cause mucopurulent discharge to reflux through the lacrimal drainage system and out the puncta.
- Evaluation of a patient who presents with epiphora should focus on determining the underlying etiology of tearing, assessing for nonobstructive causes (eg, ectropion, reflex tearing, conjunctival infection or inflammation) and nonbenign entities (eg, nasolacrimal malignancy, granulomatosis with polyangiitis). Elements of the history and exam with this focus in mind include the following:
 - A history including duration since tearing onset, percentage of the day it occurs, how it interferes with activities of daily living, and whether any particular activities provoke it (eg, cold, heat, wind, visual tasks such as computers or reading). Any history of facial trauma, prior episodes of dacryocystitis, radiation, or chemotherapy should be elicited. The patient should also be asked about bloody tears, which would be a concerning sign for underlying malignancy.
 - Prior to instilling any eye drops, the tear meniscus height should be noted, and the tear breakup time should be measured, as a cue to whether dry eye–related reflex tearing is contributing to the patient’s epiphora.

- Eyelid structures and position in relation to the globe should be assessed for concurrent disease states such as ectropion, entropion, and trichiasis. The upper and lower puncta should be examined for patency and position relative to the globe. Lower lid tone should be evaluated for degree of laxity.
- A dye disappearance test can be performed on patients of any age. A fluorescein eye drop is instilled in each eye. Normal nasolacrimal drainage will allow the dye to flow through the punctum, such that the yellow dye disappears from the ocular surface in a matter of minutes. Patients with nasolacrimal outflow obstruction show delayed clearance of fluorescein.
- In adults, the lacrimal system should be probed and irrigated. Passage of saline into the nose and throat with ease and no reflux signifies a patent system. Reflux of irrigant signifies obstruction, and the pattern of reflux can reveal where the obstruction is located within the system. Reflux from the same punctum that is being irrigated indicates obstruction within the canaliculus. Reflux from the opposite punctum without mucus indicates obstruction at the common canaliculus. Reflux from the opposite punctum with mucus indicates obstruction in the nasolacrimal sac or duct.
- Periocular skin may show erythema, edema, and breakdown of superficial tissues when the discharge or tearing is profuse and constant.
- Finally, nasal evaluation should be performed. This may reveal deviated septum, polyposis, or tumors as a cause of obstruction. Nasal mucosa may also show erythema and edema indicating chronic sinus inflammation.

DIFFERENTIAL DIAGNOSIS

- Congenital glaucoma: When the only symptom is epiphora in a child, one must always rule out congenital glaucoma. The classic triad for congenital glaucoma is blepharospasm (involuntary squeezing of the eyelids closed), photophobia (uncomfortable sensitivity to light), and epiphora. Other findings suggestive of glaucoma include buphthalmos (enlarged globe and corneal diameter) and Haab striae (breaks in the innermost layer of the cornea, leading to corneal haze). If concern for congenital glaucoma exists, the child should be referred to pediatric ophthalmology.
- Dry eye: Epiphora due to dry eye will typically occur when the patient is engaged in a visual task such as reading or computer usage, which decreases their blink rate and exacerbates the dryness of the ocular surface. The patient experiences blurring, burning or foreign body sensation, and then tear flow. Symptoms are worse in hot, dry, or windy conditions.

- Trichiasis: Growth of eyelashes from malrotated lash follicles or metaplastic Meibomian oil gland orifices results in lashes rubbing and irritating the ocular surface, which provokes tearing. Penlight exam can locate these lashes, which can be treated with epilation or more permanent methods such as cryotherapy or radiofrequency ablation.
- Conjunctivitis: Infection or inflammation of the conjunctiva can cause epiphora and ocular discharge. On examination, patients with conjunctivitis will show injection and papillae or follicles, which appear as fine bumps on the normally smooth conjunctival surface.
- Eyelid ectropion or entropion: Poor eyelid position or lax lower eyelid tone can lead to epiphora. An eyelid with normal tone smoothly sweeps the tears across the ocular surface with each blink, pumping them down the punctal drains into the lacrimal sac. Lax eyelids that are rotated outward (ectropion) or inward (entropion) cannot serve this function effectively, so the unpumped tears spill over the lid margin onto the cheeks.

IMAGING

- The diagnosis of NLDO is based on patient history, elevated tear meniscus, and obstruction observed when the system is probed and irrigated. Imaging is not often needed for diagnosis.
- In select cases, maxillofacial computed tomography (CT) and magnetic resonance (MRI) scans are helpful to evaluate the anatomy after craniofacial injury, in patients with significant sinus or nasal disease, or to evaluate for neoplasia.
- Less commonly, two methods for specific mapping of the lacrimal drainage system itself can be employed:
- In contrast, dacryocystography, in which dye is injected into the punctum and CT or MRI imaging, is used to define the anatomic details of the lacrimal drainage system outlined by the contrast agent, allowing precise location of the obstructed site(s).
- Dacryoscintigraphy uses radionuclide eye drops to follow tear flow as a gamma camera takes multiple pictures of the outflow system.

SURGICAL MANAGEMENT

- As mentioned, most congenital NLDO resolves with nonsurgical management.
 - Approximately 10% of children with congenital NLDO require probing of the duct. A small subset of those may require repeat probing with balloon

dilation of the duct, infraction of the inferior turbinate, and/or placement of silicone stents within the nasolacrimal system to relieve their obstruction.

- Because of the high success rate with these methods, dacryocystorhinostomy (DCR) is rarely needed in the pediatric population. It is reserved for children who have persistent tearing following intubation, recurrent dacryocystitis, or craniofacial abnormalities with bony obstruction of the duct.
- In adults, however, DCR is the preferred primary surgery for NLDO after the other causes of tearing have been eliminated or addressed.

FIG 2 • Algorithm for management of epiphora due to nasolacrimal duct obstruction.

- The DCR operation can be performed in three ways (**FIG 2**):²⁻⁴
- External DCR: An incision is made through the skin overlying the lacrimal sac, allowing external access to the lacrimal sac fossa for bone removal, sac opening, and stent placement under direct visualization without the need for endoscopic camera equipment.
- Literature reports a slightly higher success rate with the external approach in certain studies. When appropriately placed, the incision heals with a very

subtle and cosmetically acceptable scar.

- Internal DCR (also known as endonasal or endoscopic DCR): Attention is brought to the middle meatus, which allows the most direct access to the lacrimal sac fossa so that the nasolacrimal duct can be bypassed. The middle meatus is visualized from within the nasal cavity, allowing removal of the nasal mucosa and the bone encasing the lacrimal sac from the inside, following by opening of the sac and retrieval of the stents.
- The reported advantages of the internal approach include the lack of a visible incision, less discomfort, faster recovery, and lower risk of compromising the lacrimal pump mechanism.
- Transcanalicular diode laser: A diode laser probe is passed through the canaliculus with its tip resting within the lacrimal sac. The laser is used to ablate the tissue of the lacrimal sac, bone of the lacrimal fossa, and a localized zone of the underlying nasal mucosa. Silicone stents are then passed through these laser-cut openings and retrieved within the nose.
- This method has no skin incision, and it enables a significantly faster operating time but reports a lower overall success rate.

Preoperative Planning

- For patients with dacryocystitis, active infection should be treated before DCR.⁵ If concern is high for significant nasal septal deviation or other nasal abnormalities, which may need to be addressed intraoperatively, ENT evaluation should be considered prior to surgery. The risk of bleeding can be proactively addressed by ensuring perioperative blood pressure control and withholding anticoagulants if allowed by the patient's primary care physician or prescribing cardiologist.
- In the preoperative area, the patient is given oxymetazoline nasal spray to help vasoconstrict and decongest the nasal mucosa. For example, the spray is administered starting about 30 minutes prior to the procedure, with one dose every 5 minutes for a total of three doses.
- In the operating room after anesthesia induction, the middle meatus is injected with lidocaine with epinephrine, then packed with pledgets soaked in oxymetazoline to provide additional anesthesia and local vasoconstriction at the site.
- Moderate sedation or general anesthesia may be used for the procedure. The decision is based on surgeon and patient preference. General anesthesia is

recommended for all pediatric cases and most adult cases.

Positioning

- The patient is positioned supine on a surgical table with an adjustable headrest. The headrest is lowered to extend the neck slightly which gives the surgeon the best access. The patient should be prepped and draped leaving adequate exposure of the eyelids and nose.

TECHNIQUES

■ Internal/Endoscopic DCR

- The surgical site is accessed through the nose, using an endoscope for visualization of the middle meatus along the lateral sidewall of the nasal passage beneath the middle turbinate (**TECH FIG 1A,B**).
- If desired, a 23-gauge light pipe can be passed through the canaliculus, bringing the lit tip to rest in the lacrimal sac. This light pipe provides a point of illumination through the tissue to help localize the lacrimal fossa (**TECH FIG 1C,D**).
- A crescent blade is used to create a three-sided flap incision through the nasal mucosa down to the bone, starting just anterior to the uncinate process and extending inferiorly the height of the turbinate (**TECH FIG 1E**). A periosteal elevator is then used to push the mucosa and periosteum away, exposing bare bone.
- Rongeurs (typically 2- and 3-mm up-biting Kerrison punches) are used to remove the bone of the lacrimal fossa and the anterior process of the maxilla (**TECH FIG 1F**) to expose the entire lacrimal sac. If necessary, a DCR drill can be employed to bur away any bone that cannot be removed with the rongeurs.
- When bone removal is complete, the light pipe and/or a Bowman probe can be passed through the canalicular system to visibly put the lacrimal sac on stretch. A sickle blade is then used to open the lacrimal sac vertically from its superior to inferior pole, allowing the probe to pass freely into the nasal cavity (**TECH FIG 1G,H**). A ball-tipped seeker probe can be used to break any adhesions within the sac, which are commonly present in patients with a

history of dacryocystitis. An antimetabolite such as mitomycin C can be applied to the sac to decrease the potential formation of scar adhesions.⁶

- Nasolacrimal stents, such as the silicone Crawford bicanalicular stent, are then passed through the upper and lower puncta and retrieved in the nose (**TECH FIG 1,I,J**). The stents remain in place for several weeks postoperatively to maintain patency of the openings during the healing process.

TECH FIG 1 • A,B. An endoscopic camera is introduced into the nasal cavity, allowing visualization of the middle meatus. **C,D.** A light pipe introduced through the punctum into the lacrimal sac can be used

to help with internal visualization of the site where osteotomy should be placed. **E.** Incision is made through the mucosa down to bone along the *white dotted line*. **F.** Kerrison rongeurs are used to remove bone from the site to create the osteotomy. **G,H.** The site is confirmed with a light pipe, then the sac is incised open, and a Bowman probe is passed. **I,J.** Silicone stent tubes are passed through the upper and lower puncta and then visualized and within the nose.

■ External DCR

- A local anesthetic is injected, then the skin incision is made 3 to 4 mm from the medial canthus, starting 2 to 3 mm above the medial canthal tendon and extending over the lacrimal sac, following the direction of the nasojugal fold (**TECH FIG 2A**).
- A hemostat is used to bluntly spread the subcutaneous tissue apart, taking care to visualize the angular artery and cauterize it if necessary. Blunt dissection is carried down to the periosteum, which is scored with a blade or Bovie cautery needle. A periosteal elevator is then used to reflect the periosteum away from the bare bone, working in a posterolateral direction to access the bone of the lacrimal sac fossa (**TECH FIG 2B**).
- The periosteal elevator or hemostats are used to break through the lacrimal bone into the nose, and then the osteotomy is enlarged with rongeurs (typically 2 mm and 3 mm up-biting Kerrison punches) (**TECH FIG 2C**). Care is taken to punch through the bone cleanly, rather than rocking the pieces to break them away. This helps avoid propagating cracks along the skull base, which can result in cerebrospinal fluid (CSF) leak. An opening of 1 to 1.5 cm should be created through the bone, spanning the entire vertical height of the lacrimal sac.
- A Bowman probe is passed through the canaliculus, and its tip is used to tent the lacrimal sac (**TECH FIG 2D,E**). While holding the sac on stretch with the probe, a sickle blade is used to open the lacrimal sac vertically from its superior to inferior pole and then to make a horizontal cutback at the superior and inferior ends of the sac incision to create an anteriorly based lacrimal sac

flap. A corresponding anteriorly based flap is then opened through the nasal mucosa using Bovie or a blade. A ball-tipped seeker probe can be used to break any adhesions within the sac, which are commonly present in patients with a history of dacryocystitis. An antimetabolite such as mitomycin C can be applied to the sac and the nasal mucosa to decrease the potential formation of scar adhesions.⁶

- Nasolacrimal stents, such as the silicone Ritleng monocanalicular stent, are then passed through the upper and lower puncta, through the opened sac, and across through the opening in the nasal mucosa and retrieved in the nose (**TECH FIG 2F**). The stents remain in place for several weeks postoperatively to maintain patency of the openings during the healing process.
- The anterior flap of the lacrimal sac is sutured to the nasal mucosal flap with interrupted absorbable sutures (eg, 5-0 polyglactin), to hold both tissues tented above the stents (**TECH FIG 2G**). The skin incision is closed with buried absorbable sutures within the orbicularis muscle (**TECH FIG 2H**) and skin sutures of choice (eg, 6-0 fast gut, skin adhesive, or 6-0 nylon to be removed at 1 week).

TECH FIG 2 • A. External DCR incision marking and injection of local anesthetic. **B.** Incision is retracted open, allowing use of a periosteal elevator to lift the lacrimal sac from its fossa. **C.** An osteotomy is created

with Kerrison rongeurs. **D,E.** A Bowman probe is advanced through the canaliculus into the sac, resulting in tenting of the lacrimal sac (*white arrow*). **F.** A monocanalicular stent is placed. **G,H.** The lacrimal sac flap is sutured to nasal mucosa with absorbable sutures, and then the skin incision is closed.

PEARLS AND PITFALLS

Internal vs external approach

- Most patients have good outcomes with either approach, determined by patient and surgeon preference.
- External approach is recommended for reoperations, patients with inflammatory disease, tight internal anatomy (eg, deviated septum toward the operative side), and patients with bleeding disorders or blood thinners that cannot be stopped.

Intraoperative bleeding

- External DCR: visualize and cauterize the angular artery if it crossed the incision site, prior to opening the osteotomy.
- Internal DCR: epinephrine-soaked pledget packing helps slow intraoperative bleeding. Suction Bovie cautery is also of use, but take care to avoid too much heat exposure to the internal site, as overlying skin burns can result.

Stent duration

- Classically, stents are kept in place for 12 wk after surgery. If two monocanalicular stents are used, one can be removed at 6 wk and the other retained until 12 wk. This gives the patient earlier relief from epiphora during the recovery phase.

POSTOPERATIVE CARE

DCR is an outpatient surgery. Once the patient is deemed stable postoperatively, he/she may be discharged home with a responsible adult. Postoperative instructions should include the following:

- Avoid straining, bending, heavy lifting, or strenuous activity for at least 1 week.
- Ice pack or cold compresses can be used for the first 1 to 2 days to limit swelling and bruising.

- Nose blowing should be avoided for the first week to decrease the risk of bleeding. To reduce the risk of nose bleed from nasal vasodilation, hot drinks and food should be avoided for the first 1 to 2 days.
- At the 1 week postoperative visit, the surgical site is evaluated for any signs of impaired healing or infection, and any nonabsorbable sutures may be removed. At 6 to 12 weeks after surgery, the silicone stent is removed in the clinic, and the lacrimal drainage system is irrigated to confirm patency.

OUTCOMES

The DCR surgery is considered successful when the patient experiences total or near-total relief from epiphora. Patients often still experience tearing under circumstances in which reflex tears are normally expected (ie, emotion, ocular surface irritation, etc.), as would any eye, which is not considered a surgical failure. Surgeries fail for a variety of reasons, most relating to formation of adhesions that block the drainage tract and prevent tears from flowing freely into the nose.⁷

- The reported success rates for external DCR range from 90% to 95%. The success rate is improved by ensuring a large enough osteotomy, suturing the lacrimal and nasal mucosal flaps to keep them from obstructing the healing tract, and keeping the stents in place for several weeks postoperatively.
- There is a wider range of reported success rates for endonasal (internal) DCR. In the hands of an experienced surgeon, the success rate has been shown to be statistically equivalent to the external approach. The success rate is improved by ensuring a large enough osteotomy, avoiding excessive soft tissue maceration of the nasal mucosa and lacrimal sac, limiting thermal injury with cautery, and keeping the stents in place for several weeks postoperatively.

Intraoperative usage of the antimetabolite mitomycin-C has been shown to decrease scar formation and thereby increase success rate of the surgery, regardless of whether an external or endoscopic approach is used.^{6,8} Postoperative mitomycin C eye drops have also been tried but with less compelling effects.⁹

COMPLICATIONS

Intraoperative

- Hemorrhage. To decrease this risk, hold blood thinners preoperatively, utilize a block that contains epinephrine, and carefully visualize the anatomy to protect major vascular structures.
- Canalicular injury. Improper probing of the canaliculi can create a false passage and damage the common canaliculus when opening the sac. This risk can be decreased by using blunt probes and only advancing them along the existing canalicular lumen where there is minimal resistance.
- Orbital tissue injury. The use of drills and rongeurs can damage the structures of the orbit. Care must be taken to establish the anatomic location of the instrument with certainty prior to engaging it for bone removal. If fat is encountered in the surgical field, that is an indication that the orbit has been entered inadvertently.
- Skull base fracture and CSF leak. This risk can be decreased by carefully studying the preoperative imaging and taking note of the skull base contours across the ethmoid sinuses. Endoscopic DCR surgeons must avoid bone removal too far superiorly, to avoid breaching the fovea ethmoidalis or breaking the cribriform plate. External DCR surgeons must avoid rocking or twisting the rongeurs during bone removal, so that the skull base does not crack. The operative site should be inspected for leakage of CSF, which will be a clear fluid slightly more viscous than saline, which tests positive for beta-2-transferrin. Appropriate postoperative neuroimaging and consultation with neurology should be pursued if there is concern that a CSF leak has occurred.

Postoperative

- Bleeding can occur postoperatively, typically from the nasal mucosal vessels. Following the postoperative care instructions outlined earlier in the chapter decreases this risk. Most postoperative bleeding is self-limited and can be stopped by holding pressure against the nose for 5 to 10 minutes. For severe or persistent bleeding, patients should be seen emergently.
- Infection. It is rare to have postoperative infection after DCR, occurring only about 1% of the time even without the use of systemic antibiotics.¹⁰ If an infection does occur, the patient should be given a course of oral antibiotics with broad coverage of typical skin and mucosal flora.
- Extrusion/loss of the silicone stent tubing. The patient should be instructed not to pick or pull at the tubing within the nose or at the eyelid puncta. If it partially extrudes, it can sometimes be carefully advanced back into place. If it fully extrudes, most surgeons advise allowing the patient to heal without the

tubing rather than returning to the operating room to place a new stent.

- Lacrimal sump syndrome. Despite a patent osteotomy and normal results on probing and irrigation, patients with sump syndrome continue to experience tearing and mucous discharge due to an intact inferior pole of the lacrimal sac, which collects a pool of drainage. The chance of this complication can be decreased by creating a large osteotomy (at least 1 cm in diameter), ensuring the bone is opened all the way down to the level of the nasolacrimal duct entrance, and fully opening the lacrimal sac down to its inferior pole so that no pocket remains to collect fluid.
- Scarring of the ostium. After DCR, the bone or soft tissue can grow closed over the osteotomy site. When this occurs, the patient's epiphora returns and surgical revision is necessary to reopen the drainage tract. The risk of this complication can be decreased by creating a large enough osteotomy, clearing away soft tissue around the lumen, and applying mitomycin C to the tissue intraoperatively.

43 Management of the Microphthalmic or Anophthalmic Orbit

CHAPTER

Sarah M. Jacobs and Christopher B. Chambers

DEFINITION

A spectrum exists ranging from small eyes to complete absence of any ocular tissue:

- Nanophthalmos is defined as a small eye with otherwise normal internal structures. The axial length of the eye is ≥ 2 standard deviations shorter than average.
- Microphthalmos is an eye with axial length less than 20 mm and additional structural abnormalities.¹
- Clinical anophthalmos describes some cases of microphthalmia in which the eye is so small that the patient appears anophthalmic. However, histopathologic examination of the tissue does identify products of optic vesicle formation.
- True anophthalmos involves the complete failure of primary optic vesicle outgrowth resulting in the absence of any detectable eye tissue.^{1,2}

ANATOMY

- Nanophthalmos: In addition to short axial length, the sclera is thickened relative to the eye, the anterior chamber angles are narrow, and the refractive error is highly hyperopic. The small eye may or may not result in a hypoplastic orbit.^{3,4}
- Microphthalmos: In addition to short axial length, the internal structures of the eye are abnormal. Microphthalmic eyes can be associated with coloboma of the uvea and/or lens, persistent fetal vasculature, Peters anomaly, glaucoma, and anterior polar cataracts. An uncommon variant, microphthalmia with cyst results from failure of the ocular embryonic fissure to close, leading to a small

rudimentary eye joined to a larger cystic cavity along the colobomatous inferonasal sclera.⁵ The orbit on the affected side is hypoplastic.

- Anophthalmos: There is complete absence of any ocular tissue. The eyelids have a small palpebral fissure, and beneath the lids a rudimentary conjunctival membrane is present covering the hypoplastic orbit.

PATHOGENESIS

- Embryologic failure of the optic vesicle to develop normally from the cerebral vesicle during the 4th to 8th week of gestation can lead to congenital absence or malformation of one or both eyes.
- Because the globe influences orbital growth, these ocular anomalies can result in orbital and facial maldevelopment as well.
- Nanophthalmos is typically sporadic, but autosomal recessive or autosomal dominant forms have been described (NNO1 on chromosome 11p and NNO3 on chromosome 2q). It can occur as an isolated disorder, or as part of a syndrome such as oculo-digital-dental syndrome (ODD), or autosomal dominant vitreoretinopathopathy with nanophthalmos (ADVIRC).⁶
- Microphthalmos occurs in approximately 10 per 100 000 live births. It can occur sporadically, with some suspected association to fetal alcohol syndrome or maternal infections during gestation, especially rubella, cytomegalovirus, and herpes simplex virus. It is estimated that over half of cases occur in conjunction with systemic abnormalities, including those occurring in the setting of chromosomal anomalies, including Trisomy 13 (Patau syndrome), Trisomy 18 (Edwards syndrome), or Wolf-Hirschhorn syndrome.⁷ In inherited cases, mutations of the SOX2 gene on chromosome 3q are frequently encountered.⁷ This condition can be associated with CHARGE syndrome (Coloboma, Heart defect, Atresia choanae, Retarded growth, Genital abnormality, and Ear abnormality), and PHACE syndrome (Posterior fossa anomalies, Hemangioma, Arterial lesions, Cardiac abnormalities, and Eye anomalies).
- Anophthalmos occurs approximately 2 per 100 000 live births. It is most often sporadic but can be associated with autosomal dominant defects of the SOX2 or RBP4 genes. Maternal deficiency of vitamin A during pregnancy can also pose a risk of anophthalmia.

NATURAL HISTORY

- Ocular volume drives the growth of the eyelids, fornices, and bony orbit. In

turn, hemifacial development parallels orbital development. Thus, a small or absent eye leads to a hypoplastic orbit that can result in deformity of the hemifacial skeleton (**FIG 1**).

- At birth, the normal newborn eye is approximately 70% of its adult size. In contrast, the newborn face is only 40% of its adult size. Rapid growth of the facial skeleton and soft tissues occurs during early childhood, with the face reaching 70% adult size by 2 years and 90% adult size by 5.5 years.⁸ The degree of orbital and facial maldevelopment is different for each microphthalmic child, depending on the amount of ocular tissue present and the trophic influence that tissue exerts.

PATIENT HISTORY AND PHYSICAL EXAMINATION

As part of the initial assessment, the following questions should be considered as they will guide further management throughout childhood:

- Is the eye present or absent?
- Is this a seeing eye?

FIG 1 • A,B. Hypoplastic orbit and hemiface secondary to left microphthalmia.

- Is the other eye present? If so, is it normal?
- Are the orbits symmetric and appropriate in size?
- Are the periocular and facial soft tissues symmetric and appropriate in size?

A coordinated multidisciplinary approach is needed for evaluation of the microphthalmic or anophthalmic child, as approximately 50%

have associated systemic abnormalities and 25% have defined systemic syndromes. This approach should include:

- Comprehensive assessment by a pediatrician is needed, with particular attention to the face, ears, and palate; feeding difficulties, which can indicate neurologic or esophageal abnormalities; the cardiac system and genital anatomy (due to association with CHARGE); and metabolic disturbances, which may indicate pituitary dysfunction due to midline brain abnormalities.
- Referral to subspecialists such as neurologist, cardiologist, endocrinologist, nephrologist, and audiologist should be arranged if indicated.
- In cases with systemic findings or a syndromic diagnosis, evaluation and counseling by a pediatric geneticist is also recommended.

Ophthalmologic exam is recommended as soon as possible within the first 2 to 3 weeks of life. This should involve:

- Complete anterior and posterior assessment of both eyes to assess orbital and ocular anatomy as well as visual function. In unilateral cases, the fellow eye may have subtle findings such as coloboma, cataract, retinal dystrophy, or optic nerve hypoplasia.⁹
- Full cycloplegic refraction should be prescribed to maximize visual acuity of seeing eyes. Eyeglasses with polycarbonate lenses should be used in order to protect the globes from trauma.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preferential gaze testing (eg, Teller cards) or pattern visual evoked potential (pattern VEP) can assess basic visual acuity in preverbal patients.
- Flash visual evoked potential (VEP) testing can evaluate for any visual-cortical function in patients with severe microphthalmia or apparent anophthalmia.⁹
- Facial photographs should be taken, including a ruler in the photo for scale.
- Imaging with ultrasound of the eye and orbit to evaluate its structure and detect ocular remnants or cysts.
- MRI for detailed assessment of the soft tissues of the orbit and brain
- Maxillofacial CT for assessment of the orbital and facial bones

NONOPERATIVE MANAGEMENT

- Management focuses on utilizing the remaining vision in one or both eyes, promoting appropriate growth of the orbit and face, and optimizing ocular appearance.
- **FIG 2** outlines a treatment algorithm to accomplish these goals according to varying degrees of severity. Parents should be counseled that a series of procedures and/or devices will be needed over time to help the orbit expand in parallel to the growth of the rest of the face.
- Certain cases can be managed nonoperatively with placement of progressively larger conformers:
 - Children with useful vision in the affected eye(s) should be fitted with a series of clear conformers to progressively expand the lids, fornices, and orbit while still allowing the eye to see through the device so that visual development can occur (**FIG 3**).
- Blind eyes measuring greater than 16 mm in length can be fitted with a series of ocular prostheses to maintain the socket while also improving the appearance of the eye.
- If an eye is unable to tolerate wearing a prosthetic shell due to mechanical irritation of the corneal surface, a graft can be placed to cover the cornea (**FIG 4**).

FIG 2 • Management framework for the microphthalmic or anophthalmic orbit.

FIG 3 • A–C. A series of progressively larger conformers can be made to maintain the socket, exerting pressure to help the orbit expand and promote appropriate facial growth. For eyes with meaningful vision, clear material is used in order to avoid deprivational amblyopia.

- More severe cases can be managed with expandable devices placed into the conjunctival sac that are then inflated or exchanged for larger devices over time:
- Inflatable chambers. A flexible chamber with an anterior port that is nonsurgically seated into the conjunctival sac (**FIG 5**). A conformer holds the implant in place. Every 2 to 3 weeks in the clinic, additional saline volume is injected through the port into the chamber.
- Self-expanding hydrogels. Hydrophilic osmotic expanders (polymethyl methacrylate/polyvinylpyrrolidone), absorb up to 2000% their weight in water, resulting in expansion of 8 to 10 times the original volume (**FIG 6**).¹⁰ Hydrogel hemispheres or spheres are placed beneath the eyelids onto the conjunctival surface and secured in place with a temporary tarsorrhaphy.^{10–12} The gel is removed and exchanged for a larger-volume insert every 2 to 3 months, usually requiring a series of 2 to 4 hydrogels over the course of 4 to 12 months for adequate expansion depending on the initial size of the orbit (**FIG 7**).

FIG 4 • A–D. To improve tolerance of the scleral shell prosthesis over the microphthalmic right eye, a mucous membrane graft is harvested from the lower lip and placed onto the ocular surface to protect the cornea.

FIG 5 • A,B. A noninvasive inflatable orbital expander. The flexible chamber is seated into the conjunctival sac with its port facing anteriorly. A conformer (shown here resting on the glabella prior to insertion) is inserted over the chamber to maintain it in place. The port can be accessed with a needle and syringe to inject saline for progressive expansion of the chamber volume.

SURGICAL MANAGEMENT

- Most cases of microphthalmia or anophthalmia require surgical management for orbital expansion. There are four goals of orbital expansion:
- Stretch the periocular soft tissue to reduce the phimosis of the palpebral fissure and enlarge the fornices. This stretching makes it possible to wear a more appropriately sized conformer or prosthesis.¹³
- Stimulate orbital bone growth. Animal models and human cases repeatedly demonstrate that anophthalmic orbital volume does not increase at a normal

growth rate.¹⁴ Placing a device that exerts pressure within the orbit is effective in stimulating expansion of the bony orbital walls.

- Promote symmetric facial growth because the craniofacial skeleton is cued by the bony orbit.¹⁵
- Create space for a more permanent orbital implant. Having a larger orbital implant enables wearing of a smaller-volume prosthetic, which often improves the comfort and appearance for the patient.

FIG 6 • A–C. Hemispheric or spherical hydrogel expanders increase in volume as they absorb water, with the potential to reach full volume within about 30 hours after implantation.

FIG 7 • A–I. Orbital growth and improved symmetry with a series of hydrogels. An infant diagnosed with bilateral anophthalmia had placement of 0.9 mL hydrogel spheres at 21 days of age. Progressive expansion of the orbit can be seen in photos from 3 to 5 months of age. At 5 months, the hydrogel was exchanged for a 1.5 mL volume. At 9 months, it was exchanged for a 2 mL volume. By 14 months of age, the orbital expansion was sufficient for placement of a dermis fat graft and subsequent fitting with ocular prostheses. Ongoing symmetric orbital and facial growth can be appreciated at 2 years of age.

FIG 8 • A–E. A young boy with right microphthalmia is treated with hydrogel expanders in the office. A 0.9-mL hemisphere is placed onto the conjunctival surface. Cyanoacrylate glue is used for temporary tarsorrhaphy of the lids to hold it in place. When the hydrogel has expanded to full volume, it is exchanged for progressively larger hemispheres (1.5 mL, 2 mL) until the desired orbital volume is achieved. A well-matched prosthetic shell can then be worn.

TECHNIQUES

- There are multiple surgical methods for achieving expansion:
 - Rigid spherical implants within the orbit. Although these have the advantage of creating direct pressure within the deep orbit to stimulate growth, they are limited by the need for multiple surgeries to place serially

larger implants to promote progressive orbital growth (**TECH FIG 1**)

- Injectable fillers. These substances allow placement of added volume into the retrobulbar orbit without significant violation of the conjunctiva. Hydroxyapatite (HA) fillers are commercially available and long-lasting, making them a viable option for socket augmentation.¹⁶ An infraciliary skin incision is made, the filler cannula is introduced and advanced to the retrobulbar space and HA is then injected along the inferolateral orbital wall. The cannula is withdrawn, and the incision is closed with absorbable suture (**TECH FIG 2**). Serial injections can be performed to add more volume as the child grows.
- Hydrogel pellets can be injected into the retrobulbar orbit (**TECH FIG 3**).¹⁷

TECH FIG 1 • Rigid spherical orbital implants—shown here in silicone, ranging 12 to 22 mm in diameter—can be placed in the anophthalmic orbit to maintain space and promote volume expansion. The implants must be surgically exchanged for progressively larger sizes to keep pace with facial growth as the child grows.

TECH FIG 2 • A–D. Retrobulbar injection of hydroxyapatite granules for orbital volume expansion through an infraciliary incision. Postprocedural CT scan demonstrates the radio-opaque filler along the inferolateral deep orbit.

- Inflatable orbital expanders. These devices are implanted into the orbit and then accessed through an external port to progressively add volume over time, thereby avoiding the need for serially exchanged conformers or implants. Early designs had a port placed beneath the scalp connected to an inflatable chamber in the orbit.¹⁸ A later design for an integrated orbital expander design involved a globe-shaped chamber with an anterior injection port implanted into the orbit and secured to the lateral orbital rim via screw-fixated titanium plate (**TECH FIG 4**). Saline injections through the anterior port inflate the chamber to accomplish gradual orbital expansion.^{15,19}

TECH FIG 3 • A–F. Hydrogel pellets are injected into the retrobulbar space under anesthesia. Sagittal CT scan shows their location and expansion. Clinical photos demonstrate orbital growth and improved hemifacial symmetry.

TECH FIG 4 • The integrated orbital expander is an inflatable globe placed as an orbital implant, screw-fixed with a bone plate to the lateral orbital rim. Serial injections with saline through the anterior port inflate the globe to promote orbital expansion.

- The device is surgically removed when sufficient volume has been achieved.
- When sufficient orbital expansion has been achieved by one of the above methods, a dermis fat graft (DFG) should be placed as an autologous long-term orbital expander.²⁰
- In infants and young children, the graft is harvested from the buttock (**TECH**

FIG 5).

- An ellipse is outlined on the skin, first with ink and then reinforced with stab incisions. The marked area should correspond to the surface area of the socket where it will be implanted.
- Dermabrasion is performed to remove the epithelium down to the level where punctate bleeding is observed from the dermal vessels.
- The graft perimeter is then incised with a scalpel. Dissection is carried down through the fat in a wide cone, such that the harvested fat area is broader than the dermal surface.
- Hemostasis is obtained with bipolar cautery and then the incision is closed in 3 layers (fat, dermis, skin) with absorbable sutures.
- The orbit is prepared with an orbitotomy incision, typically oriented horizontally aligning with the palpebral fissure.
- The DFG is tucked into the orbit through this incision and then the dermis is sutured edge to edge with the conjunctiva using absorbable sutures (**TECH FIG 6**).
- After the graft is secured along its entire perimeter, a conformer is placed and the lids are closed with temporary tarsorrhaphy.

TECH FIG 5 • A–D. Dermis fat graft harvest. Buttock is marked with an ellipse. The outline is reinforced with stab incisions and then dermabrasion is performed to remove epithelium. The dermis is incised with a blade and then broader dissection is carried down through fat.

TECH FIG 6 • A–F. Dermis fat graft implantation. An orbitotomy is made through the conjunctiva, allowing insertion of the dermis graft into the orbit. The graft is secured edge to edge with conjunctiva to reform the socket surface. A conformer is placed over the graft and then the lid is closed with a temporary

tarsorrhaphy. The dermis conjunctivalizes as it heals, creating a stable surface for prosthetic wear.

PEARLS AND PITFALLS

Multidisciplinary approach	■ Ophthalmology, pediatrics, and relevant subspecialties (genetics, neurology, ENT) work together to optimize care outcomes.
Minimize surgical encounters	■ Repeated transconjunctival surgery creates traumatic conjunctival scarring, which impedes good results. ■ The risks of repeated general anesthesia to the neurocognitive development of young children are still uncertain.^{21,22}
Retaining hydrogels	■ Conjunctival hydrogel placement can be performed in the office with topical anesthesia, using cyanoacrylate glue rather than sutures to tarsorrhaphize the lids (FIG 8).
Dermis fat grafts	■ For bilateral cases, a single larger ellipse can be harvested then divided in two. ■ As the fat volume can be unwieldy during graft placement, placing the sutures systematically at the cardinal points first (12 o'clock and 6 o'clock and followed by 3 o'clock and 9 o'clock) helps retain the graft in the orbit during insertion. ■ In contrast to DFG in adults, fat atrophy does not occur to a significant degree in pediatric dermis fat grafts.
Trends in treatment	■ Management of the microphthalmic or anophthalmic orbit is moving toward goals of fewer invasive procedures, less exposure to anesthesia, and maximum symmetric growth. ■ At present these goals are best accomplished via serially larger conjunctival hydrogels, followed by dermis fat graft after sufficient expansion is achieved.

OUTCOMES

- Expansion of the bony orbit by surgical or nonsurgical means can enable near-normal facial growth, thereby improving cosmesis.
- Expansion of the eyelids and conjunctival fornices can enable wearing of an ocular prosthesis, which further improves cosmesis.

- Serial conformer therapy only directly expands the anterior orbital soft tissues, but the pressure created does induce some secondary expansion of the bony orbit. In one series of 61 microphthalmic eyes in 44 children, satisfactory symmetry was achieved in 21 cases with conformer therapy alone.¹³
- The sequence and timing of treatments must be tailored to each child to achieve the best outcome.

COMPLICATIONS

- Inadequate expansion, with residual hemifacial hypoplasia.
- Contracted conjunctival fornices, with inability to wear prosthesis.
- Infection, exposure, or extrusion of orbital implant.
- Secondary hypertrophy of dermis fat graft, requiring later debulking.

Section X: Nasal Reconstruction

44

CHAPTER Nasal Tip Hemangioma

T. Kwan-Wong and Jugpal S. Arneja

DEFINITION

- Infantile hemangiomas is a benign, proliferative, vascular tumor of infancy that has a defined, although unpredictable natural history.
- Infantile hemangiomas is the most common pediatric benign tumor, affecting between 4% and 10% of children in their 1st year of life.¹
- Approximately 60% of infantile hemangiomas involve the head and neck regions,² and of these, a small percentage affect the nose.
- Nasal tip hemangioma can cause significant deformity, affecting the psychological and emotional well-being of the patient and the family.

ANATOMY

- Nasal contour is determined by draping of the nasal skin over a framework formed by the nasal bones in the cephalic third, by the upper lateral cartilages in the middle third, and by the paired lower lateral cartilages and the caudal septum in the caudal third.
- Nasal tip hemangioma usually resides in a subcutaneous plane—although cutaneous manifestations are not uncommon—and can extend between the medial crura of the lower lateral cartilages and occasionally into the columellar region as well.^{3,4}
- Hemangioma extending between the lower lateral cartilages tends to splay the medial and middle crura of the lower lateral cartilages from each other and can occasionally dislocate the lower lateral cartilages, by displacing the cephalic edge of the cartilage into the nasal passage.

PATHOGENESIS

- Infantile hemangiomas is histologically characterized by proliferating endothelial cells with varying luminal sizes, which tend to be smaller during the proliferative phase, becoming larger during the involutional phase.
- Involution is reflected by slowing of endothelial proliferation, apoptosis of existing endothelial cells, and replacement of vascular tissue with adipocytes and connective tissue.

NATURAL HISTORY

- Infantile hemangiomas is not present at birth but becomes apparent within the first few weeks of life.
 - The initial presentation of an infantile hemangioma may manifest as a localized telangiectasia, blanched spot, or area of ecchymosis.^{1,2,5,6}
- The natural course of infantile hemangioma is relatively predictable:
 - The proliferative phase (0 to 1 year) is characterized by rapid growth.
 - The involutional phase (until 7 to 10 years) when the hemangioma shrinks and fades
 - Complete involution in 50% of children at 5 years of age, 70% by 7 years^{5,7}
 - Nasal tip hemangiomas is slower to regress than those in other parts of the body.
 - Involutional phase (greater than 10 years) when the involutional process has completed
 - Even after involution, there are often residual stigmata such as residual fibrofatty tissue, atrophic/redundant/telangiectatic skin, and persistent deformity of nasal cartilage in about 50% of patients.³⁻⁷

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be obtained, including information about onset, progression, prior treatments, and symptoms of the nasal tip hemangioma.
- Physical examination (**FIG 1**)
 - Local—size, location, distortion of nasal cartilages, involvement of nasal vault, skin quality, presence of any scars, signs of active infection, ulceration.

FIG 1 • A,B. A bulbous, pigmented hemangioma is evident at 6 months of age. (Reprinted from Arneja JS, Chim H, Drolet B, Gosain AK. The “Cyrano nose”: refinements in surgical technique and treatment approach to hemangiomas of the nasal tip. *Plast Reconstr Surg.* 2010;126:1291, with permission.)

- Regional—determine presence of any other lesions. Assess for any airway, visual, or auditory involvement that may necessitate earlier intervention.
- Systemic—rare with isolated infantile hemangioma of the nasal tip
 - Beardlike distribution may indicate airway involvement.
 - Large plaquelike distributions may suggest PHACES syndrome.

IMAGING

- Imaging is usually not required.
- Ultrasound may be useful to delineate flow within and the depth of the lesion.
- MRI may be used to delineate the extent of the hemangioma and its relation to the underlying nasal framework.

DIFFERENTIAL DIAGNOSIS

- Hemangioma
- Vascular malformation (lymphatic, venous, arteriovenous)
- Dermoid cyst

NONOPERATIVE MANAGEMENT

- Nonoperative options are usually considered as adjunctive rather than definitive treatments.
- Mainstay of nonoperative management is propranolol and corticosteroid

therapy.^{1-3,8}

- Propranolol is first-line medical therapy, and many practitioners feel this medication to be superior to oral corticosteroid treatment alone.
 - Dosing—1 to 3 mg/kg/d divided into TID dosing
 - Rare complications include hypoglycemia and limb cyanosis, while almost never bronchospasm and hypotension.
- Oral or intralesional steroid therapy ideally is used during proliferative phase (**FIG 2**). Steroid therapy can be administered for up to three treatment cycles.

FIG 2 • A,B. After completion of treatment with intralesional steroids and pulsed dye laser therapy, the lesion has decreased in size and cutaneous manifestations have resolved in the patient in FIG 1, shown here at age 3 years. (Reprinted from Arneja JS, Chim H, Drolet B, Gosain AK. The “Cyrano nose”: refinements in surgical technique and treatment approach to hemangiomas of the nasal tip. *Plast Reconstr Surg.* 2010;126:1291, with permission.)

- Can slow and sometimes arrest growth, but has little effect on regression. Response is usually seen within 1 week of initiating treatment.
- Oral corticosteroid—2 to 3 mg/kg/d of prednisolone for 8 weeks
- Intralesional corticosteroid—20 mg of triamcinolone directly into the lesion

SURGICAL MANAGEMENT

- Although precise timing of surgery is controversial, several principles exist:
 - Children begin experiencing psychosocial stigma from their peers around the

age of 5 to 7 years. Consequently, surgical correction is usually timed prior to school age.^{3,4,6,7}

- Surgical correction is usually preceded by adjuvant medical therapy to reduce the size.
- Surgery is usually not undertaken prior to the involutional phase unless the hemangioma causes significant airway obstruction and normal skin quality is important (see **FIG 1 & 2**).¹

Preoperative Planning

- Type of approach is determined based on the location of the lesion to be debulked or resected and orientation of the skin redundancy to be resected.
- Determine if any lower lateral cartilage or columellar reorientation or reconstruction is needed.

Positioning

- The patient is positioned supine on the operating table with a shoulder roll and neck hyperextension. Limbs and pressure points are adequately padded and protected.

Approach

- Techniques differ principally with respects to scar placement and ability to control transverse and vertical skin excess.
- The open tip rhinoplasty is the generally preferred technique because it permits good visualization of the entire nasal tip, as well as excellent control of both horizontal and vertical dimensions.
- The nasal subunit approach attempts to hide the incisions within the junctions of the nasal subunits, providing good control of horizontal skin redundancy but with limited vertical control.
- The Rotterdam (extended L rhinotomy) trades more extensive scarring for excellent access to the nasal tip and dorsum and is useful in controlling extreme cutaneous redundancy.
- Epinephrine containing local anesthetics should be used prior to skin incision. It provides hydrodissection, hemostasis, and postoperative analgesia.

TECHNIQUES

■ Open Tip Rhinoplasty Approach

- A transverse transcolumellar incision is made at the junction of the middle and distal thirds of the columella (**TECH FIG 1**).
 - This incision may be adjusted proximally toward the columellar-lip junction if the hemangioma extends into the columella.
- Extended rim incisions are made, connecting to the columellar incision medially and proceeding along the length of the alar rim laterally.
 - The rim incision should be kept close to the nasal skin of the alar rim to avoid resection of vestibular lining, which can cause rim retraction.

TECH FIG 1 • Markings for an open tip rhinoplasty approach. The transcolumellar incision is connected to alar rim incisions to provide access to the nasal tip and dorsum.

■ Nasal Subunit Approach

- An incision is planned along the lateral aspect of the nasal dorsum, curving around the junction between the nasal tip and ala before proceeding medially and inferiorly around the medial aspect of the soft tissue triangle and into the lateral columellar region (**TECH FIG 2**).
- Depending on the size and location of the hemangioma, it may not be necessary to use the full length of the incision.

TECH FIG 2 • Markings for the nasal subunit approach. The full incision may not be needed depending on what areas of the nose need to be accessed.

■ Rotterdam/Extended L Rhinotomy Approach

- Markings are made for an inferior rhinotomy. Starting from the alar-cheek sulcus, the proposed incision follows the alar rim before traversing the columella and across the contralateral alar rim and then cranially along the alar-cheek sulcus.
- The extended L component is then marked by connecting the inferior rhinotomy markings with a line that courses cephalically along the

nasomaxillary junction before curving medially across the nasion (**TECH FIG 3**).

TECH FIG 3 • Markings for the Rotterdam/extended L rhinotomy.

■ Elevation and Resection of the Hemangioma (Open Tip Rhinoplasty Approach)

- Using tenotomy or sharp-tipped scissors, the hemangioma with its overlying skin is dissected free from the lower lateral cartilages (**TECH FIG 4A**).
 - If the hemangioma invades the nasal columella, dissection should proceed between the medial crura of the lower lateral cartilages.
- Using sharp scissors or a no. 15 blade scalpel, hemangioma and fibrofatty tissue is sharply resected from the nasal skin in a subdermal plane (**TECH FIG 4B**).
 - Caution should be taken throughout to ensure that sufficient thickness of nasal skin remains for flap perfusion and to avoid inadvertently “button holing” through the skin.
 - A finger may be placed on the superficial surface of the nasal skin to

provide constant tactile feedback regarding the depth of resection.

- If the hemangioma involves vestibular lining, it is preferable to allow it to naturally involute to avoid alar rim retraction, which can result from overaggressive resection in this area.

TECH FIG 4 • A. Dissection of the hemangioma begins in a plane between the hemangioma and nasal cartilage. **B.** Sharp excision of the hemangioma from the overlying nasal skin, ensuring uniform and adequate skin flap thickness, with lower lateral cartilage reconstruction.

■ Lower Lateral Cartilage Reconstruction

- The shape and position of the lower lateral cartilages are assessed.
- If the lower lateral cartilage has been dislocated by the hemangioma, it should be resuspended to the upper lateral cartilage using sutures.⁵
- Interdomal sutures using 6-0 polydioxanone (PDS) are placed to reapproximate the medial and middle crura of the lower lateral cartilages if they have been splayed apart by the hemangioma (**TECH FIG 4A**).
- Transdomal sutures are placed using 6-0 PDS to restore domal projection if the intercrural angle has been flattened by mass effect of the hemangioma (**TECH FIG 4B**).

■ Skin Resection and Closure (Open Tip Rhinoplasty)

Approach)

- The nasal skin is redraped over the cartilaginous framework, and the redundant skin is marked out and sharply trimmed (**TECH FIG 5A**).
 - Skin resection should be conservative to avoid undue tension, which can produce nasal distortion, blunting of the nasal tip, or alar rim retraction.
 - With the open rhinoplasty approach, vertical skin excess can be corrected by adjusting the resection at the tip of the columellar flap, whereas horizontal skin excess can be controlled by adjusting the margin of resection at the columellar-rim flap.⁵
- The skin is approximated using rapid absorbing 5-0 polyglactin 910 (Vicryl Rapide), and if alar rim incisions were used for access, the vestibular lining is closed using 5-0 polyglactin 910 (Vicryl) (**TECH FIG 5B**).
 - If alar rim incisions were used, a silicone-conforming stent is inserted into the nares and secured using tape.

TECH FIG 5 • A. The nasal skin is loosely redraped over the nasal framework, and the skin excision is marked. Markings should err toward being more conservative to avoid undue tension during closure, which can cause nasal distortion. **B.** The final result after hemangioma excision, reconstruction of the lower lateral cartilages, and excision of resultant skin excess. Following this, Silastic-conforming stents are inserted and secured with tape.

PEARLS AND PITFALLS

Timing	■ Surgery should be delayed until involution is completed and/or cutaneous manifestations are resolved, unless there is airway/visual axis obstruction or life-threatening symptoms. ■ Surgery should be completed prior to school age to minimize the psychosocial impact experienced by the patient and parents.
Nonsurgical therapies	■ Propranolol should be considered for first-line medical therapy. Reduction in volume and color is often seen within 24–48 hours of initiating therapy. ■ Adjunctive corticosteroid therapy may be used in an intralesional or oral fashion. ■ Pulsed dye laser can be used to treat telangiectatic skin changes.
Surgical access	■ Location of the hemangioma and the vectors of skin excess will help determine the type of incision used. The authors prefer the open tip rhinoplasty approach for its exposure and ability to control both horizontal and vertical skin excess. ■ Use of local anesthetic with epinephrine provides hemostatic, analgesic, and hydrodissective benefits.
Hemangioma resection	■ If the hemangioma involves vestibular lining, it is preferable to leave residual hemangioma in these areas and to allow it to involute naturally. ■ Overaggressive resection of tumor can cause nasal tip blunting, nostril-tip disproportion, or a “skeletonization” appearance of the lower lateral cartilages.
Lower lateral cartilage reconstruction	■ Reconstruction and reapproximation of the lower lateral cartilages using domal creation and/or interdomal sutures may be necessary, especially if the hemangioma is large and/or involves the columellar region.
Minimize risk of alar rim retraction	■ If alar rim incisions are to be used, stay close to the cutaneous rim to avoid resecting vestibular lining. ■ Skin resection should be conservative, with closure being done under virtually no tension. ■ Silicone intranasal conforming stents should be used for 3 months post-operatively.

POSTOPERATIVE CARE

- If alar rim incisions are made, silicone intranasal stents should be placed

intraoperatively and left in place for at least 3 months to minimize the effects of scar contraction.

- Sutures should not be used to hold the stent in due to the risk of inadvertent columellar trauma if the suture is pulled through.
- Parents should be taught how to remove the stents for cleaning of the surgical site and how to replace and resecure the stents using tape.
- Scar massage may be started approximately 4 weeks following surgery.

OUTCOMES

- Good cosmetic results with high patient and parental satisfaction can be expected following resection of nasal tip hemangiomas (**FIG 3**).^{3,4,7}
- There is rarely a risk of recurrence if the resection is performed after the proliferative phase has passed.
- Families should be prepared for the possibility of secondary procedures such as repeat resection, scar revision, and laser therapy for cutaneous sequelae or secondary rhinoplasty.

FIG 3 • Surgical correction was performed on the patient in FIGS 1 and 2 at 5 years of age and served to “sculpt” the final appearance of the nose. **A,B.** The postoperative result is shown 1 year later. Combined medical and surgical management resulted in an optimal aesthetic result in this patient. (Reprinted from Arneja JS, Chim H, Drolet B, Gosain AK. The “Cyrano nose”: refinements in surgical technique and treatment approach to hemangiomas of the nasal tip. *Plast Reconstr Surg*. 2010;126:1291, with permission.)

COMPLICATIONS

- Infection
- Hematoma
- Necrosis of skin flap margins
- Alar rim retraction and/or stenosis
- Poor nasal tip definition
- Nasal tip distortion
- Hypertrophic/keloid scarring

CHAPTER Nasal Septal Hematoma

Whitney L. Quong and Jugpal S. Arneja

DEFINITION

- Hematoma of the nasal septum is a relatively rare, yet potentially serious consequence of trauma to the nose where blood accumulates between the cartilaginous/bony portion of the septum, and its overlying mucoperichondrium/mucoperiosteum. Any degree of craniofacial trauma should urge evaluation for the condition.
- Without prompt recognition and intervention, a septal hematoma may precipitate future cosmetic distortion, including secondary infection, resulting in septal abscess and/or ultimately a saddle nose deformity.
- Incision and drainage is the mainstay of treatment, but immediate reconstruction with autograft or homograft is an option if there is structural defect in the nasal septum.

ANATOMY

- The nasal septum comprises cartilaginous, membranous, and bony components (perpendicular plate of the ethmoid, vomer, premaxilla, maxillary crest, and palatine crest) covered by mucoperichondrium and mucoperiosteum layers (**FIG 1**). The septum is typically 2 to 4 mm thick.
- The blood supply of the nasal septum is derived from the sphenopalatine and the anterior and posterior ethmoid arteries, along with contributions from the superior labial artery (anteriorly) and the greater palatine artery (posteriorly). These vessels travel in the overlying mucous membrane and penetrate the mucoperichondrium through vascular canals. It is through diffusion that the cartilaginous septum receives its blood supply. The Kiesselbach plexus (Little area) is a region where the chief blood supplies to the internal nose converge

and is found in the anteroinferior third of the nasal septum.

- Bleeding into the potential space between the cartilage and its overlying mucoperichondrium leads to a septal hematoma (**FIG 2**), whereas external bleeding from Kiesselbach plexus results in epistaxis.

PATHOGENESIS

- Nasal septal hematoma typically results from trauma to the nasal complex, with even minor trauma causing the condition. Rarely, chronic irritation of the septum by nasogastric tube has also been found to precipitate the condition.¹
- Children are particularly prone to developing septal hematomas, as the pediatric cartilage is soft and prone to buckling,² and the mucoperichondrium is only loosely adherent to the underlying cartilage.¹
- The precise mechanism for development of nasal septal hematoma has not been defined, but has been proposed to occur when mechanical force to the nasal cartilage precipitates leakage or rupture of the mucoperichondrial vessels in the septum.
- If the mucosa remains intact, extravasated blood strips the mucoperichondrium and/or mucoperiosteum from cartilage/bone as it accumulates within a closed space.
- Where vessel compromise is coincident with fracture of the septal cartilage or bony components, blood may dissect through the fracture and form a hematoma.

FIG 1 • The nasal septum is formed by cartilaginous, membranous, and bony components.

FIG 2 • A septal hematoma is formed when there is accumulation of blood into the potential space between the cartilaginous septum and the overlying mucoperichondrium.

NATURAL HISTORY

- When not promptly recognized, extravasated blood continues to expand between the perichondrium and cartilage. Eventually, the increased pressure causes collapse of the vessels supplying the septal cartilage. Pressure-induced ischemia, avascular necrosis, and liquefaction can result rapidly within 24 to 72 hours.
- Where there is significant necrosis and destruction of the septal cartilage, the structural integrity of the septum is compromised, and a saddle nose deformity may be the end result.
- Necrosed tissue may also act as a nidus for infection and abscess development. Bacteria isolated from septal abscesses are predominantly those species of the normal nasal flora, which include *Staphylococcus aureus*, *Streptococcus pneumoniae*, group A β -hemolytic streptococcus, and *Haemophilus influenzae*.³ Collagenases produced by these bacteria serve to accelerate cartilage liquefaction.
- Meningitis, cerebral abscess, subarachnoid empyema, and cavernous sinus thrombosis have also been reported as complications of septal hematomas.³
- Because the development of septal hematoma may be delayed up to 48 to 72 hours from initial trauma,¹ sequential evaluation is recommended.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Though relatively rare—occurring as a consequence to only 0.8% to 1.6% of nasal traumas¹—one should be suspicious for septal hematoma when there is any history of craniofacial trauma.
- A full head and neck examination should be performed to evaluate for any coincident injuries. In children, the possibility of abuse must be explored.
- On history, progressive nasal obstruction is the most commonly reported symptom. Report of facial pain/headache, epistaxis, and fever are also common symptoms. Clinical features elucidated on physical examination that increase the pretest probability include hyperemia of the nasal mucosa, enlargement of the septum, swelling/ecchymoses of the nasal dorsum, external nasal deformity, and purulent rhinorrhea.¹ Presence of any of these features should prompt further history about preceding nasal trauma, upper respiratory tract infections, or dental procedures.
- With nasal septal hematoma on the differential diagnosis, focused intranasal examination of the nasal septum is required. Direct anterior rhinoscopy to evaluate the nasal septum may be performed with nasal specula. In addition to the septum, the inferior turbinate, a portion of the middle turbinate, and

possibly the nasopharynx should be visualized. Both sides of the nasal septum must be evaluated.

- The nasal mucosa is normally pink, without ulcerations, crusting, or bleeding. The septal hematoma is visualized as a lateral bulging (unilateral, or bilateral), with purple/dusky fluctuance. Palpation of the septum, by inserting a gloved finger into the nostril, may aid identification of a fluctuance. If such fullness persists even after topical administration of a vasoconstrictive agent such as oxymetazoline, the diagnosis of septal hematoma is highly likely.

IMAGING

- If the diagnosis is an isolated nasal septal hematoma, without other indication, no further imaging studies are required.
- If the septal hematoma has further developed into a nasal septal abscess, computed tomography scanning of the head and neck region with contrast enhancement should be considered to evaluate for intracranial extension. Particularly, where there is extensive facial cellulitis, focal neurologic defects, altered consciousness, meningismus, severe headache, failure to improve with treatment, delay in diagnosis and treatment, or isolation of an unusual/virulent microorganism, further radiologic imaging is recommended.⁴

DIFFERENTIAL DIAGNOSIS

- Nasal septal abscess
- Deviated nasal septum
- Nasal septal polyp
- Nasal fracture

NONOPERATIVE MANAGEMENT

- In a cooperative patient presenting soon after injury and where necrosis and infection are not suspected, the hematoma may be evacuated in the clinic or emergency department. Under local anesthetic, a simple aspiration with needle (**FIG 3**) and syringe can be performed, and the nose subsequently packed and reassessed 48 to 72 hours later.

FIG 3 • A needle and syringe can be used to enter the hematoma and evacuate the accumulated clot.

- For a more organized hematoma, incision and drainage in the operating room is suggested.
- In a pediatric patient, if significant necrosis is suspected, or if immediate reconstruction is likely to be required, management in the operating room with incision and drainage under general anesthetic is recommended.

SURGICAL MANAGEMENT

- Antibiotics should be administered upon identification of a septal hematoma. Coverage should include the common upper respiratory tract microorganisms, with amoxicillin-clavulanate recommended for uncomplicated cases, and clindamycin used where abscess is suspected or known.
- If there is compromise to the structural integrity of the nasal septum, as is commonly seen with delayed identification of a hematoma or abscess, immediate reconstruction can be considered. This is particularly supported in the pediatric population, for whom loss of portions of the cartilaginous septum may ultimately have a long-term effect on the growth of the facial skeleton.⁵

Preoperative Planning

- To anesthetize the septum, pledgets soaked in an equal part mixture of 4% lidocaine and 0.05% oxymetazoline should be packed into the nares. Adequate contact of the pledgets with the septum should be ensured. After 10 minutes, a small amount of 1% or 2% lidocaine with epinephrine can be injected into the septum.

Positioning

- Place the patient supine, ensuring adequate access, visualization, and lighting of the nasal septum.

Approach

- After the septum is anesthetized, thorough examination of septum should be permissible. With a nasal speculum, the full extent of the hematoma should be evaluated, and both sides of the septum visualized.

TECHNIQUES

■ Aspiration

- With a needle attached to a syringe, pierce the hematoma and aspirate the cavity. Blood should be amenable to being withdrawn with little force. If there is concern regarding infection, send the aspirate for culture and sensitivity. This step may also be performed in the clinic/emergency department if the diagnosis is unclear, or as a temporizing measure prior to operative management.

■ Hemitransfixion Incision

- A hemitransfixion incision is made at the junction of the membranous septum and the lower border of the nasal septal cartilage to further explore and evacuate the hematoma. Residual clot should be suctioned, and the cavity irrigated with saline. Necrotic cartilage should also be debrided. Subsequently, any defect in the cartilage can be assessed, and the need for reconstruction considered.

■ Septum Reconstruction

- Defect in the septal cartilage following debridement of the necrotic tissue can be reconstructed immediately. In this case, the surgeon may consider converting to an open tip approach for direct access to the nasal base and septum; the precise amount of the cartilage defect can be evaluated, and approach for reconstruction considered.
- Three principal methods of cartilage reconstruction are advocated: the “exchange technique” using posterior septal components to reconstruct the anterior defect, a “mosaicplasty” piecing together residual cartilage with fibrin glue, and reconstruction with a cartilage autograft or homograft.⁷
- An “exchange technique” is suitable where larger pieces of cartilaginous/bony septum remain in the posterior septum.
 - From the dorsal portion of the septum, a portion of the cartilage can be harvested and implanted into the defect as an autogenous septal graft.
 - Guide sutures may be used to position the graft into anatomic position, and transverse mattress sutures used for fixation.
 - If a defect still exists, and there is insufficient cartilage, a graft from the osseous septum may also be taken.
 - This exchange technique is not recommended in children, however, because disruption of the posterior septum may ultimately affect septal and midface growth.
- For multiple small cartilaginous septal components underlying the hematoma—that is the septum has fractured but not necrosed—a “mosaicplasty” can be performed. In this technique, the septal fragments are held together with fibrin glue and used to patch the defect. Although relatively simple, it has been suggested that this technique may not be the most effective in preventing or treating a saddle nose deformity.⁶
- A cartilage autograft or homograft is possibly the most preferred method of reconstruction. Cartilage is typically consistent, appropriately elastic, amenable to shaping, and typically heals uneventfully. There is debate as to its ideal source, with conchal, tragal, costal, or preserved donor cartilage being options.
 - When using preserved donor cartilage, there is typically not as significant limitation in size or volume as in comparison to employment of an autograft. Although different constructions including the “L-shaped” and

“angular-shaped” types have been described, possibly the “boomerang-shaped” (**TECH FIG 1**) design is the most preferred. The boomerang shape is proposed to best resist mechanical stress, as it provides supports to both the Little area, as well as the anterior nasal spine.⁶ Ultimately, if a graft is used, it should be fit to the size of the defect and provide support to the nose.

TECH FIG 1 • The boomerang-shaped cartilage graft provides support to the anterior spine and Kiesselbach plexus area and is resistant to mechanical stress.

■ Preventing Reaccumulation: Drain, Wick, or Quilt

- A few different measures are available to prevent reaccumulation of the hematoma. Into the hemitransfixion incision, an iodoform wick can be inserted, or a penrose drain may be stitched in place (**TECH FIG 2A**). Alternatively, and preferred, a quilting stitch (with an absorbable suture) can be performed, which runs back and forth across the septum in a random pattern to firmly press the mucoperichondrium against the cartilage and eliminate dead space (**TECH FIG 2B**).

TECH FIG 2 • To prevent reaccumulation of the hematoma, **(A)** a penrose drain may be stitched into place temporarily, or **(B)** a quilting stitch (with an absorbable suture) can be performed to firmly press the mucoperichondrium against the cartilage and eliminate dead space.

■ Nasal Packing

- Vaseline gauze packing is placed with or without suturing of the mucosa to the septum.

PEARLS AND PITFALLS

Bilateral hematoma incisions

- For bilateral septal hematomas, the hemitransfixion incisions should be staggered/nonopposing, as to avoid a through-and-through perforation of the septum.

Securing the cartilage graft

- To further secure the cartilage graft into the defect in an effort to avoid migration, silicone sheets can be placed on the mucosa, and mattress sutures used through the silicone sheet, mucosa, perichondrium, and cartilage graft. The sheets may be kept in place for up to 10 days.

POSTOPERATIVE CARE

- If infection was present, the patient should be monitored for fever, worsening facial cellulitis, increasing pain, and changes in mentation in the immediate postoperative period. Emergence of any of these features should prompt re-exploration of the hematoma and drainage of fluid, alteration on the antibiotic regimen, or CT scan to evaluate for intracranial involvement as necessary.
- The head of the bed should remain elevated to reduce edema and pain.
- For noninfected patients, the nasal packing and drain/wick should be kept in place for 72 hours before removal. At that time, re-evaluation is recommended to ensure no recurrence of the hematoma.
- Follow-up at 1 year is recommended to evaluate for saddle nose deformity. In children, ongoing follow-up may be necessary to assess growth of the nose.

OUTCOMES

- Large outcome studies of nasal septal hematoma treatment are not available. However, the data seem to suggest a significant rate of long-term complications.
- One study of 16 pediatric patients (7 with nasal septal hematoma, 9 with nasal septal abscess) with a mean follow-up period of 3 years found minor sequelae in 6 patients (minor cosmetic deformity, minor septal/vault alterations without airway compromise), and major sequelae in 10 patients (dorsum/tip/pyramid deformation with important cosmetic impairment, deviation of the septum with nasal obstruction, swelling of the septal cartilage, functional vault deformity, septal perforation).⁷ Another study using this classification system found a long-term complication rate of 63% patients with nasal septal hematoma and 89% in patients with septal abscess.¹
- One review of 8 articles discussing outcomes of early nasal septal reconstruction in the management of nasal septal abscess reported sequelae in 11 of the total 28 patients.⁵ These complications included underdevelopment of the nasal tip and premaxilla in one patient undergoing homologous reconstruction, minimal saddle deformity in one patient with homologous reconstruction, nonobstructing deviation of the nasal septum in four patients with homologous/exchange reconstruction, columellar retraction in one patient with autologous reconstruction, and three patients with over-rotation of the nasolabial angle after autologous reconstruction. One patient also developed saddle nose deformity, upward displacement of the anterior maxilla,

diminished vertical development of the nasal cavity, and a retrognathically positioned maxilla after reconstruction with homologous tissue.

FIG 4 • The saddle nose deformity is one long-term cosmetic complication of cartilage collapse post-untreated septal hematoma.

COMPLICATIONS

- Nasal septal abscess, leading to meningitis, orbital cellulitis, intracranial abscess, cavernous sinus thrombosis, or oronasal fistula
- External deformity of the nose: saddle-nose type (**FIG 4**), tip over-rotation
- Growth inhibition of the midface in children, leading to underdevelopment of the nose and maxilla, midface retroposition, or retracted columella
- Nasal obstruction
- Septal deviation
- Septal perforation

Section XI: Pediatric Neck Masses

46 Branchial Cleft Sinuses and Cysts

CHAPTER

Mark Felton, Jugpal S. Arneja, and Neil K. Chadha

DEFINITION

- Spectrum of congenital sinuses and cysts due to developmental anomalies in the branchial system.^{1,2}
- Account for up to 17% of cervical neck masses.³

ANATOMY

- Branchial arches are akin to ancient gill apparatus (**FIG 1**).
- Humans have five branchial/pharyngeal arches, 1 to 4 and 6 (there is no 5th branchial arch), which form craniocaudally from week 4.
- Membrane ectoderm externally and endoderm internally covers the arches.
- Cleft externally separates each arch.
- Pouch internally separates each arch.
- Each arch forms an artery, cartilaginous structure, nerve and muscle.
- Arches 1 and 3 mainly form the face, and arches 3, 4, and 6 form the neck, with 4 and 6 fusing.
- Ectodermal clefts obliterate except for the 1st branchial cleft, which forms the external auditory canal with outer side of the tympanic membrane forming the medial limit.
- Branchial pouches form various head and neck organs (Tables 1 and 2).

FIG 1 • Branchial arch and pouches.

PATHOGENESIS

- Failure of branchial pouch or cleft to obliterate during embryonic development can lead to fistula, sinus, or cyst formation:
 - A cyst is an epithelial-lined fluid-filled sac.
 - A sinus is a blind-ended epithelial lined tract opening on to skin or mucosa.
 - A fistula is an epithelial-lined tract connecting two surfaces (skin/mucosa).
- The resultant anomaly from failure of this process relates to the specific arch, pouch or cleft derivatives.
- The main branchial anomalies associated with sinuses and fistulae are 1st and 2nd cleft anomalies and 3rd and 4th pouch anomalies.
- Type 1 branchial anomalies are rare anomalies resulting in duplication of the external ear canal and are classified as Work's type 1 or 2.
- Branchial cleft cysts are regarded as 2nd branchial anomalies. Several theories

exist as to their origin including³:

- Lymph node inclusion theory—cystic transformation of lymph nodes
- Branchial cleft remnant theory—remnant of branchial cleft/pouch
- Thymopharyngeal duct theory—remnant of the connection between the thymus and 3rd pouch
- Cervical sinus of His theory—cyst is formed by remains of the cervical sinus.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Branchial sinuses and fistulas may present as a discharging neck punctum +/- neck swelling.
- Type 1 branchial anomaly is rare.
 - Often a late diagnosis
 - May present with a mass in parotid or submandibular region
 - Discharging neck punctum or discharging ear
- Type 2 branchial anomalies are the most common branchial anomaly.
 - Often present at or just after birth
 - External opening in the skin (punctum) along anterior border sternocleidomastoid muscle +/- discharge
- Type 3 and 4 branchial sinus
 - Neonates—lateral neck cyst/abscess +/- airway obstruction
 - Child/young adult—thyroiditis/recurrent neck abscess
 - Most commonly diagnosed in childhood (delayed diagnosis)
- Branchial cysts
 - May present as a cystic neck swelling +/- infection/abscess

Table 1 Branchial Arch and Pouch Derivatives

	Arch Derivatives				Pouch Derivatives
	Artery	Cartilage	Cranial Nerve	Muscle	
1	Part of terminal branches maxillary artery	Meckel cartilage: malleus and incus, anterior malleolar ligament, mandible template,	V—trigeminal	Muscles of mastication, mylohyoid, tensor tympani, anterior belly digastric	Tubo-tympanic recess, tympanic cavity, mastoid antrum, Eustachian tube

		maxilla, zygomatic bone and squamous temporal bone, mandible			
2	Stapedial arteries	Reichert cartilage: stapes, styloid process, stylohyoid ligament, lesser cornu, and superior body of hyoid	VII—facial	Muscles of facial expression, stapedius, stylohyoid, posterior belly digastric	Tonsils
3	Common carotid arteries, internal carotid arteries	Greater cornu and inferior part of hyoid	IX— glossopharyngeal	Stylopharyngeus	Inferior parathyroid glands and thymus
4	Left forms part of aortic arch, right forms part right subclavian artery	Laryngeal	X—vagus, superior laryngeal	Cricothyroid, pharynx constrictors	Superior parathyroid glands and possibly the calcitonin- producing cells of thyroid
6	Pulmonary arteries, ductus arteriosus	Laryngeal	X—vagus, recurrent laryngeal	Intrinsic muscles of larynx	

■ Peak age 3rd decade

- Most are located anterior to the upper part of the sternocleidomastoid muscle
- Branchio-oto-renal syndrome is an autosomal dominant syndrome with a prevalence of 1 in 40 000 people. It is caused by mutations in the *EYA1*, *SIX1*, and *SIX5* genes.⁴
- Children born with this typically have branchial anomalies, ear abnormalities (including pits, tags, atresia, hearing loss) and kidney abnormalities (including hypoplastic/absent kidneys). If suspected, these children require audiometry, an ultrasound of the renal tract, and genetic counseling.

IMAGING

- Imaging varies depending on the branchial anomaly.
- Cysts—ultrasound (USS) is obtained usually, but an MRI may be helpful when the diagnosis is not clear on USS.
- Type 1—CT to image middle ear and MRI for soft tissues and course of sinus/fistula (**FIG 2A**).
- Type 2—clinical diagnosis; usually no imaging required.
- Types 3 and 4—barium swallow/and direct laryngoscopy to assess for sinus/fistula entrance at the pyriform fossa; USS +/- MRI to assess thyroid involvement and any cystic component (**FIG 2B**).

Table 2 Pathophysiology and Sinus/Fistula Course

FIG 2 • A. MRI of type 1 branchial fistula. **B.** Sinogram of type 3 branchial sinus.

DIFFERENTIAL DIAGNOSIS

- Type 1 anomaly—parotitis, parotid tumor.
- For an infected/discharging type I branchial fistula, atypical mycobacterium is a differential to be considered.
- For neck swelling associated with type 3/4 branchial anomaly—lymphatic malformation, thyroiditis, abscess, lymph nodes.
- Branchial cysts—lymph nodes, abscess, lymphatic malformation, dermoid.

NONOPERATIVE MANAGEMENT

- Watchful approach may be opted for initially in very young children and those who are asymptomatic or have only minor symptoms.
- Treat any infections with antibiotics and avoid incision and drainage because this may lead to a persistent discharging fistula and/or make future surgical excision more challenging due to scarring.
- The majority will require surgical treatment.

SURGICAL MANAGEMENT

Preoperative Planning

- Review relevant imaging.
- Examine the patient preoperatively to check if the swelling/sinus/fistula is still present.
- Antibiotics are not routinely required for noninfected cases.
- Facial nerve monitoring should be used for type 1 branchial anomaly excisions.

Positioning

- Supine on head ring, with shoulder roll to extend neck
- Table in reverse Trendelenburg for hemostasis (head 30 degrees above feet)

Approach

- For branchial fistulas, type 2 branchial sinuses, and branchial cysts, the treatment of choice is open excision.
- Type 1 fistulas should be removed by a superficial parotidectomy approach. Type 1 branchial cleft fistulas may enter the middle ear or external auditory canal and therefore should be managed in conjunction with an otolaryngologist.

- For types 3 and 4 sinuses with a piriform sinus opening, the mainstay of treatment is now endoscopic sinus ablation via suspension laryngoscopy, usually performed by an otolaryngologist.⁵ If initial endoscopic treatment fails, open resection with possible hemithyroidectomy may be required.

TECHNIQUES

■ Excision of Type 1 Branchial Fistula

- The facial nerve monitor is used throughout the procedure.
- Rotate the neck away from the lesion.
- The neck is prepped with aqueous Betadine. Drape the patient, leaving the ear, angle of mandible, and operated side of face exposed. The temple and side of mouth should be left exposed so as to see the facial muscles twitch, and a clear sterile drape can be used to cover the face.
- A modified parotidectomy incision (cervico-mastoid-facial incision) is marked out, descending from the anterior to the tragus, around the earlobe, continuing down the neck toward the fistula site and finishing by making an ellipse around the fistula punctum/wound.
- The incision site is infiltrated with 1% lidocaine with 1 in 100 000 epinephrine (**TECH FIG 1A**).
- The skin is then incised with a no. 15 blade, and the ellipse of the skin around the punctum is removed.
- Subplatysmal flaps are raised inferiorly and superiorly and retracted using silk stay sutures. A further stay suture is also used retract the earlobe back (**TECH FIG 1B**).
- Dissect around the fistula punctum and any inflamed tissue to reveal a fistula tract.
- Using a fine artery clip, carefully dissect the parotid gland from the tragal cartilage and mastoid tip, exposing the tympanomastoid suture.
- Next attention should be turned to finding the facial nerve by dissecting with an artery clip and microbipolar forceps over the tragal cartilage toward the tragal pointer. The fascia over the sternocleidomastoid muscle is also freed and the posterior belly of the digastric muscle is found deep to the sternocleidomastoid muscle. When dissecting over the upper 1/3 of the

sternocleidomastoid muscle, the greater auricular nerve will be encountered and the posterior branch of this nerve may need to be sacrificed (**TECH FIG 1C,D**).

- Note that the facial nerve may be displaced inferiorly and medially by the fistula. Use the facial nerve stimulator to aid in finding the facial nerve. The nerve is usually found:
 - 5 mm deep to the tympanomastoid suture
 - 1 cm deep and inferior to the tragal pointer
 - At the level of the posterior belly of digastric muscle
- This main branch of the facial nerve is traced to the bifurcation of upper and lower branches, using a fine artery clip and microbipolar forceps (or a blade) to remove the tissue superficial to the nerve. The artery clip is advanced along the nerve with blades open when dividing parotid tissue above the nerve for good visualization of the nerve. The upper and lower branches of the nerve are traced in same manor to free them from the fistula tract as required. The fistula tract will run in close proximity to the nerve, with the possibility of branches going both lateral and medial to the fistula.
- If it is difficult to find the facial nerve trunk, retrograde dissection may be performed, initially by tracing the fistula tract from the punctum and finding the nerves overlying the tract and then tracing them back to the main trunk in a retrograde fashion.
- Once facial nerve branches are dissected from both above and below the fistula, the surgery progresses to removing the fistula tract, slowly elevating the tract from over the inferior branches of the facial nerve and carefully sliding the tract from beneath any overlying branches.
- The fistula tract is dissected from surrounding tissue using microbipolar forceps and traced to its origin, which may be into tragal cartilage, the cartilaginous part of the outer external auditory canal, the bony part of the external ear canal, middle ear, or a combination of these (**TECH FIG 1E**).
- If the fistula ends at the tragus or cartilaginous canal, it can be separated from the cartilage and the area allowed to heal by secondary intention.
- If the fistula enters the bony ear canal and middle ear, which will be evident on CT scanning and preoperative examination, the case should be performed with someone skilled in Otologic surgery. Middle ear exploration, tympanoplasty, and possible bony canalplasty may need to be performed to fully remove the tract.

TECH FIG 1 • Excision of type 1 branchial fistula. **A.** Incision planned to excise scar/granulation tissue around the fistula; the skin is infiltrated with 1% lidocaine with 1 in 100 000 epinephrine. **B.** Subplatysmal skin flaps are raised, and then the priority is to locate the main trunk of the facial nerve and follow its branches. **C.** Facial nerve branches are seen coursing both over and under the fistula and are traced and freed from the fistula. **D.** The fistula is dissected from lower facial nerve branches on its undersurface. **E.** Once free from the facial nerve, the fistula is traced to its origin at the tragal cartilage and external ear canal/middle ear. The neck component of the fistula is excised prior to removing the

middle/external ear component of the fistula.

- Once the fistula is fully removed, the wound is closed. Exposed facial nerve may be covered by loosely apposing parotid tissue with 4/0 Vicryl sutures. Platysmal muscle edges are also apposed with interrupted buried 4/0 Vicryl sutures. No drain is required.
- The skin can be closed with a continuous running subcuticular 5-0 Prolene suture. Both ends of the Prolene suture should be left 1 to 2 cm long outside of the skin to facilitate removal. ¼ in. 3M Steri-Strips (St. Paul, MN) are applied to the wound with the cut ends of the suture hidden beneath.
- The patient can be discharged the same day once they are eating and drinking.
- No postoperative antibiotics are required.

■ **Excision of Type 2 Branchial Sinus/Fistula (TECH FIG 2)**

- The neck is prepared with aqueous Betadine.
- Drape the neck so as to square off the operative site, leaving the neck exposed from below the punctum to the mentum and lateral to the sternocleidomastoid muscle.
- Mark a small horizontal ellipse around the punctum.
- Inject 1% lidocaine with 1 in 100 000 epinephrine around the incision site.
- Use a lacrimal probe placed gently through the punctum to identify the sinus/fistula tract and confirm that it runs upward in the classic pattern toward the tonsillar fossa.
- Incise an ellipse of the skin around the punctum and dissect on to the tract using the microbipolar forceps. The lacrimal probe can be left in the tract to help follow the tract. Dissect along the tract superiorly using the microbipolar forceps. Keep close to the tract as it may course over the hypoglossal nerve and between the internal and external carotid arteries. If access is restricted, an endoscope or further separate superior “step-ladder” incision may be used to improve visualization of the tract.
- The tract is traced through the defect in the mylohyoid muscle. An artery clip and a 3-0 Vicryl tie are applied above the level of mylohyoid; the tract is

then cut and sent for histology.

- The skin can be closed with a continuous running subcuticular 5-0 Prolene suture. Both ends of the Prolene suture should be left 1 to 2 cm long outside of the skin to facilitate removal. ¼ in. 3M Steri-Strips (St. Paul, MN) are applied to the wound with the cut ends of the suture hidden beneath.
- The patient can be discharged the same day once they are eating and drinking.
- No postoperative antibiotics are required.

TECH FIG 2 • Excision of type 2 branchial anomaly.

■ Endoscopic Management of Type 3/4 Branchial Sinuses

- The patient is intubated.
- Suspension laryngoscopy is performed using an age-appropriate Parsons laryngoscope. The laryngoscope is positioned to visualize the pyriform fossa (**TECH FIG 3A,B**).
- If a sinus is identified then a flexible bugbee monopolar cautery needle (size 4/5 French) is placed into the sinus and used to ablate the tract (set at 4–6 watts). Two to three passes of the cautery tip are usually required (**TECH FIG 3C,D**).
- The laryngoscope is then removed and the surgery complete.
- The patient is observed for any signs of airway compromise on the day unit and discharged once they are eating and drinking.
- If endoscopic ablation fails initially, it may be repeated. If revision endoscopic surgery fails, the patient will typically require open excision of the cyst/sinus/fistula with possible hemithyroidectomy.

TECH FIG 3 • Endoscopic ablation of type 3 branchial anomaly. **A,B.** Endoscopic photograph of the left pyriform fossa showing start of type 3 sinus tract. **C,D.** Ablation of the tract with Bugbee cautery (4–6 watts).

■ Excision of Branchial Cyst

- Rotate the neck away from the side of the cyst.
- The neck is prepared with aqueous Betadine.
- Drape the neck so as to square off the operative site, leaving the neck exposed from below the supraclavicular notch to the angle of the mandible and lateral to the sternocleidomastoid muscle.
- Mark a horizontal incision over the swelling but at least 2 cm below the angle of the mandible. This will avoid damage to the marginal mandibular nerve as it runs superficially.
- Inject 1% lidocaine with 1 in 100 000 epinephrine around the incision site.
- Incise the skin, through platysma and raise upper and lower subplatysmal flaps. The flaps are retracted back using either a self-retaining retractor or

silk sutures.

- Identify the anterior edge of the sternocleidomastoid muscle and instruct your assistant to retract this posteriorly.
- You should then identify the cyst. Dissect the cyst from the surrounding tissue using microbipolar forceps, being careful not to damage or puncture the cyst wall. The hypoglossal nerve, accessory nerve, jugular vein and carotid arteries may be in close proximity to the cyst and therefore dissecting on the cyst wall will avoid damage to these structures.
- Once all edges of the cyst are freed the cyst can be removed. Bipolar cautery should be used for hemostasis.
- The platysmal muscle edges are apposed with interrupted buried 4-0 Vicryl sutures. No drain is required.
- The skin can be closed with a continuous running subcuticular 5-0 Prolene suture. Both ends of the Prolene suture should be left 1 to 2 cm long outside of the skin to facilitate removal. ¼ in. 3M Steri-Strips (St. Paul, MN) are applied to the wound with the cut ends of the suture hidden beneath.
- The patient can be discharged the same day once they are eating and drinking.
- No postoperative antibiotics are required.

PEARLS AND PITFALLS

Diagnosis	■ Given the number of differential diagnoses for and complex surgical anatomy of branchial anomalies, a combination of imaging methods may be required to formulate a diagnosis. ■ The standard for diagnosing a type 3 or 4 branchial anomaly is direct laryngoscopy of the pyriform fossa under general anesthetic.
Incision	■ For type 1 fistulas use a modified cervico-mastoid-facial incision, excising the skin punctum and surrounding inflamed tissue in the same incision. ■ Place incisions parallel to or over skin creases where possible.
Hemostasis	■ Use of microbipolar forceps for cutting tissues allows accurate dissection with effective hemostasis. ■ Prior to skin closure, place patient in Trendelenburg position and ask anesthetist to perform a Valsalva maneuver on the patient to raise

	venous pressure and assist identification of any potential bleeding sites.
Dissection	■ In performing open branchial sinus/fistula or cyst excisions, stay close to and dissect on the cyst/tract to minimize damage to surrounding structures.
Closure	■ Closing the final skin layer with interrupted subcuticular 5-0 Prolene and 3M Steri-Strips (St. Paul, MN) removed at 10–14 days after surgery minimizes tissue reaction seen through use of absorbable skin sutures.

POSTOPERATIVE CARE

- Surgery is performed as outpatient surgery with discharge on the same day.
- Advice to keep wound dry.
- Postoperative antibiotics are not usually required, unless there is active infection at the time of surgical excision.
- Review with patient at 10 to 14 days with histology results and for removal of subcuticular Prolene skin suture and 3M Steri-Strips (St. Paul, MN).
- Follow up as an outpatient 3 months postoperatively.

OUTCOMES

- Recurrence rates:
 - Type 1—less than 2% although greater for middle ear involvement
 - Type 2—less than 2%
 - Type 3—The success rate for endoscopic management of pyriform fossa sinus tracts was 89.3% overall in a recent review (90.5% in primary cases and 85.7% in revision cases).⁵

COMPLICATIONS

- General—bleeding, infection
- Type 1—risk of injury to facial nerve (temporary/permanent) and potential complications from middle ear exploration (perforation tympanic membrane, hearing loss, temporary altered taste due to damage to chorda tympani nerve)
- Type 2—risk of injury to hypoglossal nerve, accessory nerve, lingual nerve
- Type 3—risk of injury to recurrent laryngeal nerve (endoscopic or open); external laryngeal nerve, parathyroid injury, hypothyroidism (open)
- Branchial cyst—vascular injury, nerve damage; marginal mandibular, vagus, hypoglossal, accessory, greater auricular

CHAPTER Thyroglossal Duct Cysts

Mark Felton, Jugpal S. Arneja, and Neil K. Chadha

DEFINITION

- The most common congenital midline neck cyst¹
- Caused by embryological remnants of thyroid gland formation

ANATOMY

- These cysts can exist anywhere from the base of tongue to the level of the thyroid gland as they form in remnants of the thyroglossal duct (**FIG 1**).
- 75% are at the level of the hyoid bone.

PATHOGENESIS

- During week 4 of embryological development, the thyroid develops between the 1st and 2nd pharyngeal pouches from floor of the pharynx at the level of the foramen cecum (posterior 1/3 tongue) (**FIG 2**).
- This becomes a bilobed diverticulum and descends through the neck to reach final position anterior to the tracheal cartilages. As it descends through the neck, it leaves a tract.
- The tract usually atrophies after 5 to 10 weeks.
- Caudal attachment of the tract may remain as the pyramidal lobe of the thyroid.
- Failure of the tract to obliterate can lead to cyst formation at any point throughout the tract length (**FIG 3**).

NATURAL HISTORY

- Thyroglossal duct cysts are present at birth but may not be clinically apparent until enlarged secondary to infection.

- They present as a midline neck swelling most commonly in childhood and adolescents.
- 90% present as midline neck swellings only, but infection and formation of a secondary discharging sinus are possible (10%).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Midline neck cyst.
- May elevate on swallowing and tongue protrusion.
- With a history of infection, there may be signs of an abscess or sinus formation with discharge.

IMAGING

- Ultrasonography of the neck and thyroid to evaluate the swelling and confirm a normal thyroid is present (**FIG 4**).
- In the absence of a thyroid gland, a thyroglossal duct cyst (TGDC) may contain the only functioning thyroid tissue.
- Nuclear imaging in the form of radioactive iodine scan can be used if there is doubt regarding normal functioning thyroid.
- Thyroid function blood tests are only required if presence of normal thyroid tissue is in question.

DIFFERENTIAL DIAGNOSIS

- Midline dermoid cyst
- Sebaceous cyst
- Midline branchial cleft cyst
- Lymph node
- Ectopic thyroid tissue
- Laryngocele
- Thyroid carcinoma within TGDC

NONOPERATIVE MANAGEMENT

- Conservative watchful waiting in children until over age 12 months
- Advise there is a risk of infection with possible sinus formation if conservative approach is taken.
- Antibiotics with possible aspiration if the cyst becomes infected and forms an abscess. It is not recommended to incise and drain an infected TGDC because this risks sinus formation with chronic discharge.

FIG 1 • Clinical photographs of anterior neck showing TGDC. **A.** Scar tissue is from previous site of infection with skin breakdown. **B.** TGDC with central discharging sinus.

FIG 2 • Thyroid development.

- Uncommonly infection and inflammation may actually lead to closure of the residual duct and resolution of symptoms.

- Theoretical risk of malignant change of thyroid tissue within TGDC if left indefinitely, with less than 1% of excised TGDCs having a primary carcinoma on histology.²

SURGICAL MANAGEMENT

Preoperative Planning

- Review ultrasound scan result to confirm that normal thyroid tissue is present in the usual location.

FIG 3 • Pathogenesis of TGDC development.

- Examine preoperatively to check that swelling is still present.
- Assess ideal level for placement of a transverse incision that will provide exposure from the level of the suprahyoid muscles to the superior border of the thyroid gland for removal of the TGDC (typically approximately midway between the palpable landmarks of the hyoid and upper thyroid notch).

Positioning

- Supine on head ring, with shoulder roll for neck extension
- Table in reverse Trendelenburg for hemostasis (head 30 degrees above feet)

FIG 4 • Ultrasound scan of TGDC (*long arrow*) overlying thyroid cartilage (*short arrow*).

TECHNIQUES

■ Modified Sistrunk Procedure

Preparation of the Neck and Wound Incision

- Antibiotics are not indicated for routine noninfected cases.
- The neck is prepared with aqueous Betadine.
- Drape the neck so as to square off the operative site, leaving the neck exposed from the mentum to below the sternoclavicular notch and the sternocleidomastoid muscles laterally.
- Mark the site of horizontal incision over the cyst, ideally midpoint between the hyoid and thyroid notch so as to allow adequate access to both the suprahyoid muscles and the pyramidal lobe of the thyroid. Initially, plan to incise skin to incorporate the width of the cyst only in case it is identified to be a dermoid cyst, in which case following a tract superiorly and inferiorly is not required and cystectomy is adequate (**TECH FIG 1A,B**)
- Inject 1% lidocaine with 1 in 100 000 epinephrine around the incision site.
- An incision is made through the skin and subcutaneous tissue. Subplatysmal flaps are elevated both superiorly to above the level of the hyoid and inferiorly to below the level of the cricoid cartilage (**TECH FIG 1C**). Take care with this step as the cyst can be superficial, making it easy to puncture, which is more likely if the cyst is large and under pressure. If a cyst is

punctured, the dissection can continue with a clip on the cyst capsule at the puncture site.

Exposure of Thyroglossal Cyst and Tract

- Once the cyst is exposed, if clinically it is a dermoid and there is no obvious tract or surrounding attachments, the cyst can be removed and skin closed. Otherwise, the cyst can be left alone and dissection of the tract performed next, with widening the skin incision for better access if required (**TECH FIG 2A**).
- Identify the infrahyoid strap muscles, usually below the cyst. Identify the midline and carefully separate the right and left strap muscles, the more superficial muscle being sternohyoid and deeper muscle being sternothyroid (**TECH FIG 2B,C**).
- Carefully dissect along the medial edge of the sternohyoid and sternothyroid muscles if necessary, separating them from the cyst. Carefully expose the medial border of the length of the infrahyoid strap muscles from their hyoid attachment superiorly as far inferiorly as the superior border of the thyroid gland. Any tissue between the infrahyoid strap muscles will be removed in continuity with the cyst and will contain the inferior tract if present.
- Look for an inferior component of the thyroglossal duct extending inferiorly from the cyst, which extends to the pyramidal lobe of the thyroid gland. If the duct extends down to the thyroid gland, remove a small cuff of pyramidal lobe with the specimen. Even if the tract is not clearly visible, it will be safely removed by removing all the tissue between the strap muscles from the cyst down to the pyramidal thyroid lobe inferiorly.

Hyoid and Tongue Base Dissection, With Specimen Excision

- After completion of this inferior dissection, ensure that the medial borders of the infrahyoid strap muscles are identified and exposed up to their attachments to the hyoid bone. The infrahyoid strap muscles are often adherent to the cyst just inferior to the hyoid bone. When there has been previous infection, a small portion of infrahyoid strap muscle may need to be left attached to the cyst and removed with the cyst and specimen. A tract arising from the superior aspect of the cyst may be seen passing into the hyoid bone, although the whole cyst may be adherent to the hyoid mid-portion.
- The superior muscular attachments of the hyoid bone (predominantly the

mylohyoid and geniohyoid) are then detached from the midportion of the hyoid bone superiorly, using the medial borders of the infrahyoid strap muscle attachments as a guide to how far to laterally dissect superiorly, thereby avoiding the hyoid lesser horns and the hypoglossal nerve.

- The central portion third of the hyoid bone is resected by cutting through the hyoid. It is imperative that this cut is precisely vertical and level with the medial borders of the infrahyoid strap muscles, lateral to the cyst or cyst tract if identified. An Allis forceps holding the central portion of the hyoid bone can help stabilize the bone. In small children, bipolar forceps are often sufficient to cut through the noncalcified hyoid, but in older children/adolescents/adults, straight Mayo scissors or even bone cutting forceps may be required cut through the hyoid bone. Cautery and bone wax can be used to stop any bleeding from the cut edges of the hyoid (**TECH FIG 3A,B**).

TECH FIG 1 • **A.** Position of TGDC, relations of the duct and position for surgical incision (midline collar incision), with the duct running through the hyoid bone and ending at pyramidal lobe of thyroid. **B.** Midline collar skin crease incision. **C.** Subplatysmal skin flaps are raised.

TECH FIG 2 • **A.** Midline dissection on the TGDC (*black arrow*) and tract (*white arrow*). **B.** Dissecting out the TGDC. **C.** The strap muscles are separated in the midline. *Arrow* indicates sternohyoid muscle.

- Now the inferior tract, cyst, and hyoid bone are free of the surrounding tissue; a superior tract arising from the superior and posterior aspect of the hyoid may be seen running into the tongue base. If present, the tract should be dissected from the surrounding tissue and followed up to the tongue base. A cuff of tongue muscle (genioglossus muscle) should always be taken with the midportion of the hyoid and the specimen to complete the excision and minimize risk of a residual superior tract. There is no need to excise tongue muscle in complete thickness through to the oropharynx, as originally described by Sistrunk (**TECH FIG 3C,D**).

TECH FIG 3 • A. Division of mid third of hyoid bone. **B.** The tract is traced to the hyoid and the hyoid (*short arrow*) is cut either side of tract in line with the medial edge of the thyrohyoid muscles (*long arrow*). **C.** A cuff

of tongue muscle is taken with the specimen. **D.**
Specimen.

- Attention should then be focused on ensuring meticulous hemostasis. The patient should be placed in the Trendelenburg position (30 degrees head down) and saline wash poured in to the wound. A prolonged Valsalva maneuver by the anesthetist will reveal any further bleeding points for cauterization.

Wound Closure

- The operating table is then placed in a neutral position for wound closure.
- The strap muscles are apposed with 4-0 Vicryl and the skin flaps closed with interrupted buried 4-0 Vicryl sutures. No drain is required (**TECH FIG 4A,B**).
- The skin can be closed with a continuous running subcuticular 5-0 Prolene suture. Both ends of the Prolene suture should be left 1 to 2 cm long outside of the skin to facilitate removal. ¼ in. Steri-Strips are applied to the wound with the cut ends of the suture hidden beneath (**TECH FIG 4C**).
- The patient can be discharged the same day once they are eating and drinking.
- No postoperative antibiotics are required.

Modifications of the Procedure

- Skin sinus tract—A skin ellipse around the sinus and ellipse of tissue around the sinus tract is taken, which should be taken in continuation with the rest of the dissection of the thyroglossal cyst. This may lead to the horizontal incision site being more superior than ideal, and the incision therefore is lengthened to facilitate the inferior access.
- Recurrent cysts—En-bloc wide local of excision around the recurrent cyst, taking a core of strap muscle on either side down to pretracheal fascia.

TECH FIG 4 • A. Suturing of infrahyoid muscles. **B.** Strap muscles reapproximated with 4-0 Vicryl sutures. **C.** Skin is closed with 5-0 Prolene and Steri-Strips.

PEARLS AND PITFALLS

Incision	Initially only make your incision the width of the swelling until the diagnosis is confirmed in case it is a dermoid cyst, for which a smaller incision will suffice. Once a dermoid cyst is excluded, the incision can be widened.
Hemostasis	- Use of microbipolar forceps for cutting tissues allows accurate dissection with effective hemostasis. - Prior to skin closure, place patient in Trendelenburg position and ask anesthetist to perform a Valsalva on the patient to raise vascular pressure and assist identification of any potential bleeding sites. Bone wax can help oozing from edges of cut hyoid bone.
Dissection	- Actively look for any extension of the cyst/duct toward the pyramidal lobe and remove a cuff of the pyramidal lobe if the duct is in continuation. - Dissect along the medial aspect of strap muscles on to the hyoid bone. Remove the hyoid at the level of the medial aspects of the strap muscles to avoid damage to the hypoglossal nerve. - Look for a tract extending from the hyoid to the tongue base, dissect along this, and remove a cuff of tongue base with the specimen.
Closure	Closing final skin layer with interrupted subcuticular 5-0 Prolene and

Steri-Strips removed at 10–14 days after surgery minimizes tissue reaction seen through use of absorbable skin sutures

POSTOPERATIVE CARE

- Day case surgery
- Advice to keep wound dry
- Review 10 to 14 days with histology and for removal of Prolene skin suture and Steri-Strips
- Follow up outpatients 3 months

OUTCOMES

- Recurrence rate of 0% to 3% for modified Sistrunk as described above may be much higher with other techniques such as cystectomy only.^{1,3}

COMPLICATIONS

- Bleeding, infection, hypertrophic/keloid scar
- Accidental pharyngostomy
- Hypoglossal nerve injury
- Recurrence—treat with en-bloc wide local excision

Section XII: Facial Reanimation

48

CHAPTER Sural Nerve Harvest

Andre P. Marshall, Jeffrey R. Marcus, and Michael R. Zenn

DEFINITION

- The sural nerve is a lower limb sensory nerve that provides sensation to the lateral and posterior distal third of the leg, lateral calcaneal region, lateral foot, and small toe.¹
- The sural nerve is easily accessible, has several large fascicles, and is the donor nerve most commonly used in peripheral nerve reconstructive surgery.^{2,3}
- Unilateral sural nerve harvests can provide up to 40 cm of autogenous nerve graft.

ANATOMY

- The sural nerve is a sensory nerve that begins in the lateral aspect of the foot and coalesces from branches between the Achilles tendon and lateral malleolus.
- The nerve splits into the medial and lateral cutaneous nerves of the leg along the posterior leg.
- The larger contributor, the medial sural cutaneous nerve, arises from the tibial nerve in the popliteal fossa between the medial and lateral heads of the gastrocnemius.⁴
- The sural nerve runs deep to the investing fascia down the posterior calf between the two heads of the gastrocnemius muscle and then subcutaneously in the distal third of the leg.
- It can be found close to, but deep to, the lesser saphenous vein to the ankle.
- It is consistently found in the space between the lateral malleolus and the calcaneus tendon.²⁻⁵

PATIENT HISTORY AND PHYSICAL FINDINGS

- Any history of prior lower extremity operation, either open or endoscopic, should be elicited from the patient.
- Physical exam should note any scars or prior incisions on the lower extremities, or numbness or paresthesias in the distribution of the sural nerve.

IMAGING

- Prior to sural nerve harvesting, no imaging of the lower extremities is necessary.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperatively, a comprehensive history and physical exam should be performed. It is imperative to note any prior lower extremity trauma, fractures, or previous operations.
- Patients should be counseled on the expected postoperative outcomes of cutaneous sensory loss in the sural nerve distribution.

Positioning

- The donor limb is placed in flexion at the knee.
- A bump, sandbag, or roll under the ipsilateral buttocks provides additional access to the posterior leg.
- In children, prone positioning is usually preferred and well tolerated.

Approach

- Open
- Endoscopically assisted

TECHNIQUES

■ Stair-Step Incisions

Video p8-c048

- The patient is placed in supine or prone position (**TECH FIG 1A**).
- An endoscope can be used to facilitate dissection.⁶
- A pneumatic tourniquet (optional) is placed around the thigh and the leg exsanguinated in the usual fashion prior to incision.
- A 2- to 3-cm transverse or vertical incision is made in the groove made by the lateral border of the Achilles tendon at the level of the lateral malleolus.
- The lesser saphenous vein is seen, retracted, and preserved.
- Blunt dissection is used to identify the nerve.
- The nerve is dissected of all surrounding tissue moving superior along the posterior calf.

TECH FIG 1 • **A.** Preoperative markings and an outline of the sural nerve and its lateral cutaneous

branch are shown. The proposed transverse incisions are shown in addition to the Achilles tendon and lateral malleolus. **B.** The sural nerve is shown following harvest along the transverse incisions.

- At approximately 10 cm, an additional 2- to 3-cm transverse incision is made more proximally along the course of the nerve.
- Proximal and distal dissection of the nerve is made through each incision.
- Up to two additional transverse incisions are made along the course of the nerve until adequate length is obtained.
- The nerve is transected at the popliteal fossa and removed from the leg (**TECH FIG 1B**).
- Incisions are closed in standard fashion, in a minimum of two layers with absorbable sutures.
- No drain tubes are necessary.

■ Harvest With a Tendon Stripper^{4,7}

- A pneumatic tourniquet is placed around the thigh and the leg exsanguinated in the usual fashion.
 - A 2- to 3-cm transverse or vertical incisions is made in the groove made by the lateral border of the Achilles tendon at the level of the lateral malleolus.
 - The lesser saphenous vein is seen, retracted, and preserved.
 - Blunt dissection is used to identify the nerve, and then transecting it up to 5 cm distal to the incision to gain additional length.
 - The cut end of the nerve is passed through a tendon stripper.
 - Mild traction is placed on the nerve, and the tendon stripper is passed proximally until its tip can be felt in the subcutaneous tissues near the popliteal fossa.
 - The stripper is twisted and counter-pressed until the nerve is felt to give way and able to slide out of the ankle wound.
 - Optionally, the leading edge of the tendon stripper is tented against the skin, a stab incision is made, across the end of the stripper to divide the nerve.
-

PEARLS AND PITFALLS

Anatomy	■ The sural nerve has many variations during its course. ■ The surgeon must be aware of the variable sural anatomy, particularly the branches of the medial and lateral cutaneous nerves.
Positioning	■ Sural nerve harvest can be done in either supine or prone position. In children, prone positioning is well tolerated and can better facilitate exposure and shorten harvest time.
Dissection	■ Avoid excessive circumferential dissection, which may place the nerve at greater risk of injury. ■ Superficial dissection is usually adequate to facilitate release from the overlying subcutaneous tissues.
Graft processing	■ In most cases, the graft is used intact. ■ Splitting of the graft into multiple grafts and preserving fascicles longitudinally has been described but is not practiced in our unit.

POSTOPERATIVE CARE

- Elastic bandages from the foot to the knee are placed and used to provide compression and help decrease hematoma formation. They are left in place for 48 hours and used thereafter for control of swelling as needed.
- Patients are encouraged to begin ambulation on postoperative day 1 to help reduce the risk of deep venous thrombosis. Full activity restrictions are kept in place for 2 weeks or dictated by the concurrent grafting procedure at the recipient site.
- Pain is minimal and managed with a combination of narcotic and non-narcotic analgesic medications.

OUTCOMES

- Scars should be expected at the donor site and are permanent. Regular scar management is recommended.
- The area of paresthesia and numbness in the ankle and foot is likely permanent but may decrease in size over time due to contributions from surrounding intact nerves.¹

COMPLICATIONS

- Postoperative complications are infrequent but include proximal neuroma formation, hematoma, and deep venous thrombosis. We have not seen cellulitis

in our patient cohort, but it is possible.

- The iatrogenic sensory nerve deficit along the lateral foot should be expected and is not considered a complication. It is generally well tolerated by patients and should be discussed preoperatively.

Cross Face Nerve Graft

CHAPTER

Michael J. A. Klebuc

DEFINITION

- Cross face nerve graft—interposition nerve graft utilized to transmit facial nerve motor axons from a neurologically intact to a paralyzed/paretic, contralateral hemiface.
- Utilized to restore motor innervation to denervated muscles of facial expression and to neurotized free, functional muscle flaps, also can be employed for sensory restoration.
- Frequently utilized sources of nerve graft (sural nerve, saphenous nerve, medial antebrachial cutaneous nerve).
- Approximately 50% of a facial nerve's zygomatic and buccal branches can be selectively transected and their function redirected to the paralyzed hemiface without producing significant donor weakness (functional reserve).
- The facial nerve is the only donor nerve that can consistently restore spontaneous, emotionally mediated facial motion.

ANATOMY

- Facial nerve (somatic motor efferent component)—innervates the muscles of facial expression, auricular muscles, occipitalis, posterior belly digastric, stylohyoid, and stapedius.
- The facial nerve main trunk emerges from the skull base via the stylomastoid foramen where it can be identified coursing 1 cm deep to the tragal pointer and medial to the posterior belly of the digastric muscle.¹
- Within the parotid gland, the facial nerve divides into a temporofacial and cervicofacial trunk.
- Distal branches exit the parotid on its anteromedial surface.

- The following branches innervate the corresponding muscles of facial expression²:
 - Frontal branch—frontalis muscle
 - Zygomatic branches—orbicularis oculi, zygomaticus major, zygomaticus minor, levator labii superioris, levator labii superioris alaeque nasi, corrugator supercilii, procerus
 - Buccal branches—buccinator, risorius, orbicularis oris
 - Marginal mandibular branches—depressor anguli oris, depressor labii inferioris, mentalis
 - Cervical branches—platysma
- Muscles of facial expression are innervated on their deep surface with the exception of the levator anguli oris, buccinator, and mentalis.
- Zuker point describes the approximate location of the facial nerve branch supplying the zygomaticus major (**FIG 1**):
 - Midway point of a line drawn from the root of the helix to the lateral commissure.
 - Preferentially divided and coapted to a cross facial nerve graft (CFNG) as the first step in a two-staged free, functional muscle flap reconstruction.³

FIG 1 • The facial nerve branch supplying the zygomatic

major is typically found at a point halfway between the root of the helix and the commissure (Zuker point).

- Pitanguy line describes the course of the frontal branch of the facial nerve. The line extending 0.5 cm below the tragus to 1.5 above the lateral brow with the nerve running on the undersurface of the temporoparietal fascia.⁴
- The marginal mandibular branches—consistently lie on top of the facial artery and vein 1 to 3 cm below the mandibular border.⁵

NATURAL HISTORY

- Axonal growth through the cross face graft proceeds at approximately 1 mm/d.
- Ten to twelve months is typically required for the axons to traverse the graft.
- After 18 months of denervation, mimetic muscles undergo significant atrophy and poor functional outcomes are associated with nerve grafting.
- A narrow time window is present for the use of cross face nerve grafts as an isolated procedure to restore innervation to the paralyzed muscles of facial expression.
- The therapeutic window of CFNG is enhanced by the addition of a nerve “babysitter.”⁶
 - Transfer of an adjacent cranial nerve to the injured facial nerve to achieve rapid reinnervation and motor end plate preservation.
 - Partial hypoglossal-to-facial nerve transfer with an interposition jump graft and secondary selective facial nerve branch transection and distal end-to-end repair to CFNG.
 - Masseter-to-facial nerve transfer with immediate CFNG and distal end-to-end and/or end-to-side coaptation.⁷

PATIENT HISTORY AND PHYSICAL FINDINGS

- Etiology of the facial paralysis:
 - Developmental
 - Traumatic
 - Post-tumor extirpation
 - Bell palsy
 - Ramsay Hunt syndrome
- Duration of paralysis:
 - Denervation periods greater than 18 months are associated with poor

functional recovery (irreversible muscle atrophy) without utilization of a muscle flap.

■ Patient age:

- Peripheral nerve regeneration declines with advanced age.
- There is no definitive age cut off for cross face nerve grafting; however, after the age of 50 to 55 years, the ipsilateral motor nerve branch to masseter or other adjacent cranial nerves often provide a more reliable source of innervation to free muscle flaps with more powerful muscle flap contraction.

■ Comorbidities impairing nerve regeneration:

- Smoking—higher risk of skin flap necrosis
- Diabetes
- Vascular disease
- Previous radiation
- Neurologic disorders

■ History of hypercoagulable state:

- Patient or family history of pulmonary emboli or deep venous thrombosis signal the need for a hematologic workup if a subsequent free, functional muscle flap is planned.

■ Physical Examination

- A strong smile, normal blink, forceful eye closure, good lip pucker, and depression without synkinesis should be present on the donor hemiface.
- Perform a complete cranial nerve exam to look for additional deficits.
- Examine the eye on the paralyzed side for signs of exposure keratitis.
- Look for previous incisions that could compromise perfusion to the cheek flaps elevated during facial nerve exploration.
- Palpate and Doppler the superficial temporal and facial artery and veins on the paralyzed hemiface if a subsequent free, functional muscle flap is planned.
- Palpate lower extremity pulses if sural or saphenous nerve grafts are to be harvested to rule out peripheral vascular disease.
- The progressive growth of axons through the CFNG can be monitored by eliciting a Tinel sign.
- An active Tinel sign at the distal end of the cross face nerve graft suggests signals readiness for the next phase of the reconstruction.

IMAGING

■ MRI of brain and facial nerve

- High-resolution multiplanar T1 and T2 images, gadolinium-enhanced, fat-

suppressed, and internal auditory canal (IAC) protocol

- Used to evaluate injury to the facial nerve (ie, Bell palsy, tumors, stroke)
- Computed tomography
 - 0.625-mm or thinner axial images, reconstructions in coronal plane
 - Valuable for imaging temporal bone fractures
- CT angiogram
 - Useful for evaluating possible sites for microvascular anastomosis in patients with multiple head-neck surgeries or developmental differences including hemifacial microsomia.
- EMG of the facial nerve
 - Look for signs of early facial nerve recovery.
 - Look for signs of reversible muscle atrophy.

SURGICAL MANAGEMENT

Preoperative Planning

- Facial nerve EMG is obtained to evaluate for irreversible mimetic muscle atrophy.
- Facial nerve imaging as guided by the etiology of the paralysis (MRI, CT, CT angiogram).
- Determine the number of cross face nerve grafts to be utilized and evaluate the potential nerve graft donor sites.
- Discontinue smoking and nicotine products.
- Discontinue anticoagulants.

Positioning

- Supine on the operating table with narrow head extension.
- Head on foam or gel-filled headrest.
- Nasotracheal intubation with endotracheal tube sutured to nasal columella and supported on the hair-bearing scalp with foam, silk tape and staples (**FIG 2**) or an Oral RAE tube secured to the lower dentition with a 2-0 silk Ivy loop suture.
- Oral cavity cleansed with chlorhexidine gluconate mouth wash.
- Sterile tourniquet applied to the thighs.
- Sterile calf sequential compression devices.

Approach

- Preauricular approach is most frequently employed.
 - Aesthetically favorable access incision especially in children and young adults
 - Permits dissection of all facial nerve branches facilitating nerve stimulation, creating of a functional map and optimal donor nerve selection
 - Allows retrograde dissection of selected facial nerve branches into the parotid gland to enhance axonal concentration
- The nasolabial fold approach is infrequently used.
 - Unaesthetic scarring in children and young adults.
 - Limited ability to select the optimal donor nerve branch.
 - Access to only distal nerve branches with more limited axon counts.

FIG 2 • Nasotracheal intubation with head positioned on a narrow head-rest. Endotracheal tube sutured to columella and supported with foam to prevent pressure on the nasal alae.

TECHNIQUES

■ Exposure and Flap Elevation

- The anterior border of the masseter muscle is palpated and marked.
- A pretragal, incision with an extension into the sideburn is now marked with a surgical pen.
- An additional point is marked half way between the root of the helix and the

commissure to indicate the general location of the facial nerve branch to the zygomaticus major muscle (Zuker point) (**TECH FIG 1**).³

- A petrolatum gauze dressing is used to occlude the external auditory canal.
- The subcutaneous tissues in the preauricular, zygomatic, and buccal regions are infiltrated with a 1:100 000 epinephrine, hemostatic solution (local anesthetics should be avoided).
- The preauricular incision with the sideburn extension is made and a skin and subcutaneous tissue flap is elevated in the preauricular, zygomatic, and buccal regions caring the medial aspect of the dissection approximated 3 cm past the medial border of the masseter muscle.
- An SMAS flap is now elevated with scissor dissection and bipolar cautery.
 - The flap is mobilized to the anteromedial border of the parotid gland where the zygomatic and buccal branches of the facial nerve are identified.
 - The SMAS flap is released transversely along the inferior zygomatic border and reflected to facilitate exposure (**TECH FIG 2**).

TECH FIG 1 • Operative markings. **A.** Preauricular incision with a possible submandibular extension (X) marks Zuker point and the *dashed lines* represent the region of skin flap elevation. **B.** Markings shown on the patient in the sample case.

TECH FIG 2 • A,B. Extent of the skin-subcutaneous flap elevation and initial SMAS flap dissection. **C.** SMAS flap elevation.

■ Nerve Mobilization and Graft Harvest

- The operating microscope is brought onto the field to enhance visualization and microsurgical dissection is used to further explore and mobilized the facial nerve branches.
- During the dissection, the transverse facial artery is often encountered. This is a useful landmark as the zygomatic branches above and below this structure often produce an excellent smile with little activation of the orbicularis oculi.
- The facial nerve branches are encircled with thin segments of microvascular background to facilitate later identification.
- Electrical stimulation is now performed. The facial nerve branches are stimulated at 0.5 to 1 mA at 40 Hz and a functional map of their activity is created.
- The largest and most powerful zygomatic branch that produces activation of the zygomatic major and levator anguli oris muscles without associated eye closure is identified.

- It is traced in a retrograde fashion into the parotid gland to maximizing its caliber (**TECH FIG 3**).
- Selective nerve branch transection at this site will be performed later in the case for smile restoration.
- If the surgical goals include restoration of eye closure, pucker and lip depression, then approximately 50% of the facial nerve branches to the orbicularis oculi, orbicularis oris, and depressor anguli oris and depressor labii inferioris are selected for eventual transection.⁸
- A submandibular extension of the initial access incision may be required to reach the marginal mandibular branches.
- Gowns and gloves are changed and new instruments are used to harvest the nerve grafts under tourniquet control.
- The sural nerve is approached via a limited access incision approximately 2 cm posterior to the lateral malleolus (**TECH FIG 4**).
- The sural nerve is separated for the lesser saphenous vein, ligated with 4-0 silk ties, and divided. A nerve stripping device (Aesculap TEK784, Aesculap Inc., Center Valley, PA) is used with a gentle back and forth twisting motion to mobilize the nerve from distal to proximal. If significant resistance is encountered, an additional counter incision is made and the tethering side branch released. Grafts measuring 25 to 30 cm are reliable harvested.

TECH FIG 3 • A. The facial nerve branches bordering the transverse facial artery are frequently selected for

transfer as they often produce an isolated smile with little or no activation of the orbicularis oculi or orbicularis oris. **B.** Isolation of zygomatic facial nerve branches.

TECH FIG 4 • Sural nerve harvested via a limited access incision utilizing a nerve-stripping device.

■ Graft Passage and Completion

- If more than one nerve graft is to be passed through an adjacent tunnel, they are marked in increments with different colored sutures to facilitate identification.
- An alligator, tendon passing clamp is inserted through limited incision in the contralateral hairline and preauricular region. The clamp is now tunneled

through either the subcutaneous or deep supraperiosteal plane, traversing the upper lip, lower lip, and submental region as determined by the number of cross face nerve grafts (**TECH FIG 5**).

- Small access incisions may be required in the upper and lower lip to successfully create the tunnels.
- These incisions can be used to identify branches of the infraorbital and mental nerves that can be selectively transected and eventually coapted to the cross face nerve graft (end-to-side) if desired in an effort to enhance axonal growth.⁹
- The nerve grafts are reversed and the proximal nerve end is ligated with a colored 4-0 nonabsorbable, monofilament suture (facilitates delayed identification).
- The tendon passing clamps are used to gently draw the graft across the face.
- The donor facial nerve branches are selectively divided, and an end-to-end nerve repair is made between the facial nerve branch and corresponding nerve graft with 10-0 nylon suture in an interrupted, epineurial fashion (**TECH FIG 6**).
- The SMAS flap is returned to its native position and secured with 4-0 absorbable suture.
- The subcutaneous pocket is treated with spray thrombin or fibrin glue, and the incision is repaired over a closed suction drain.
- The nerve graft donor site access incisions in the extremities are closed in layers with absorbable, monofilament suture and covered with cyanoacrylate tissue adhesive. The incisions are covered with ABD pads and elastic bandages are utilized to support the feet and calves.
- Antibiotic ointment is applied to the head and neck incisions and no dressings are applied.
- A deep, atraumatic, extubation is then coordinated with the anesthesiologist.
- Foot sequential compression devices are applied for deep venous thrombosis prophylaxis.

TECH FIG 5 • Creating of subcutaneous tunnels with alligator clamps for passage of cross face nerve grafts.

TECH FIG 6 • **A.** Cross face nerve grafts for restoration of eye closure and smile with proximal and distal end-to-end nerve repairs. **B.** Cross face nerve graft in situ. **C.** End-to-end nerve repair between sural cross face nerve graft and a zygomatic branch of the facial nerve.

PEARLS AND PITFALLS

Facial nerve branch selection

- For smile restoration, select the largest facial nerve branch that produces isolated activation of the zygomaticus major without associated eye closure.
- Trace the nerve branch into the parotid gland to increase the axon density.

Nerve graft injury

- If significant resistance is met when harvesting the graft with a nerve-stripping device, an additional incision should be created.
- The obstructing side branch is then transected to prevent accidental nerve graft avulsion.
- Failure to do this may result in a graft of inadequate length with disruption of the internal architecture.

Hemostatic solutions

- Avoid local anesthetics that contain epinephrine as they will impair nerve conduction and the ability to create a functional map.
- A solution of 1:100 000 epinephrine will achieve good vasoconstriction without impairing nerve conduction.

Avoid aesthetic complications

- Short-acting muscle relaxants are only permitted on induction, if essential.
- The need to avoid muscle paralysis must be communicated during changes of anesthesia providers.
- Deep, atraumatic, extubation without compressive, face mask ventilation.

POSTOPERATIVE CARE

- Patient is maintained a clear liquid diet for 48 hours followed by a soft diet for 4 weeks.
- The oral cavity is rinsed with chlorhexidine gluconate mouth wash twice a day for 7 days, after which an electric tooth brush is utilized for oral hygiene.
- Pressure on the cheeks is strictly avoided.
- Incentive spirometry is avoided and patients are encouraged to deep breathe. A pinwheel can be used to encourage pediatric patients to breathe deeply.
- Ambulation with assistance is usually initiated on the first postoperative day and pedal sequential compression devices are utilized while in bed.
- Anticoagulation is generally avoided due to the potential increased risk of facial hematoma.

- No strenuous exercise or heavy lifting for 6 to 8 weeks following surgery.
- Elastic bandaging of the lower extremities is employed for 2 to 3 weeks to reduce edema and improve patient comfort.

OUTCOMES

- The ability of cross face nerve grafts to successfully innervate free, functional, muscle flaps for smile restoration has been demonstrated in multiple publications over the past two decades.⁷
- Although the reconstructed smile is spontaneous, it is frequently weaker than that achieved with a muscle flap innervated by the motor nerve to masseter.¹⁰
- The ability of CFNGs to deliver an adequate axonal load decreases with age, and alternate strategies are often employed for individuals in the sixth and seventh decades of life.
- Cross face nerve grafting as an isolated technique rarely produces adequate strength to achieve symmetric facial motion.
- Cross face nerve grafts can be used with a distal end-to-side coaptation to enhance the power of paretic muscles of facial expression.¹¹

COMPLICATIONS

- Potential weakening of the unaffected hemiface following selective transection of facial nerve branches.
- Hematoma formation requiring evacuation and potential disruption of the nerve grafts.
- Cheek skin flap necrosis (patients should be counseled on smoking cessation and avoiding nicotine).
- Neuroma formation at the nerve graft donor site.
- Failure of adequate nerve regeneration.
- Sialocele, salivary fistula, and parotitis.
- Otitis external resulting from blood collecting in the external auditory canal.
- Compartment syndrome after sural nerve graft harvest.

50 Motor Branch of Masseter for Innervation of Free Muscle Flap

CHAPTER

Michael J. A. Klebuc

DEFINITION

- The descending branch of the motor nerve to the masseter muscle (CN V) can be selectively divided and employed to innervate free muscle flaps, utilized for smile restoration.

ANATOMY

- The masseter nerve branches from the mandibular nerve and passes above the lateral pterygoid muscle where it runs through the mandibular notch to enter the substance of the masseter muscle.
- Along its intramuscular path, the main trunk liberates a series of small proximal branches and terminates in a long descending branch that courses obliquely in posteroanterior, proximal-distal trajectory.
- The main trunk of the masseter nerve can be identified at a point 3 cm in front of the tragus, 1 cm below the zygomatic arch, and 1.5 cm deep to the SMAS (**FIG 1**).¹
- The masseter muscle has three lobes (superficial, middle, and deep).
- The motor nerve to the masseter (CN V) lies on the superficial surface of the deep lobe.²
- The main trunk and descending branches contain approximately 2700 and 1550 myelinated motor fibers, respectively.^{1,3}

FIG 1 • Topographic landmarks for masseter nerve isolation. Main nerve trunk located 3 cm in front of the tragus, 1 cm below the zygomatic arch, and 1.5 cm deep to the SMAS.

- The descending branch of the masseter nerve is usually selectively transected and employed to innervate free muscle flaps utilized for facial reanimation.

PATHOGENESIS

- The masseter nerve is frequently selected as a source of innervation in cases of bilateral facial paralysis and when the facial nerve is unavailable as a donor (ie, Moebius syndrome, Lyme disease, bilateral temporal bone fractures, brainstem cavernous malformation, Guillain-Barré).⁴
- Often selected over cross face nerve grafts in older patients where the potential for nerve regeneration is diminished.⁵

PATIENT HISTORY AND PHYSICAL FINDINGS

- Etiology of the facial paralysis:

- Developmental
- Traumatic
- Post-tumor extirpation
- Bell palsy
- Ramsay Hunt syndrome
- Patient age:
 - Peripheral nerve regeneration declines with advanced age.
 - There is no definitive age cutoff for cross face nerve grafting; however, after the age of 50 to 55 years, the ipsilateral motor nerve branch to masseter or other adjacent cranial nerves often provide a more reliable source of innervation to free muscle flaps with more powerful muscle flap contraction.
- Comorbidities impairing nerve regeneration:
 - Smoking—higher risk of skin flap necrosis
 - Diabetes
 - Vascular disease
 - Previous radiation
 - Neurologic disorders
- History of hypercoagulable state:
 - Patient or family history of pulmonary emboli or deep venous thrombosis signals the need for a hematologic workup prior to free, functional muscle flap reconstruction.
- The patient's level of motivation and willingness to comply with postoperative physical therapy is also important to ascertain.
- History of temporomandibular joint dysfunction—consider alternative technique.

Physical Examination

- Active, forceful, contraction of the masseter and temporalis muscles is confirmed by palpation.
- The face is examined for previous access incisions and signs of trauma or injury to the muscles of facial expression.
- Dental occlusion and mouth opening are evaluated to rule out temporomandibular joint dysfunction.
- A cranial nerve examination is performed to identify additional neurologic deficits.
- Palpate and Doppler the superficial temporal and facial artery and veins on the

paralyzed hemiface to verify patency.

IMAGING

- Imaging studies are seldom required in the presence of a normal physical examination.

SURGICAL MANAGEMENT

Preoperative Planning

- Smoking cessation and avoidance of nicotine
- Discontinuation of oral anticoagulants
- EMG
 - Concomitant activation of the masseter muscle with attempted smiling (may predict development of an effortless smile)⁶
- Mark the nasolabial folds and smile vectors prior to entering the operating room.

Positioning

- Supine on the operating table with arms tucked
- Narrow head extension with foam- or gel-filled headrest.
- Nasotracheal intubation with nasal ray endotracheal tube sutured to the columella and supported on the hair-bearing scalp with foam, silk tape, and staples (**FIG 2**)

FIG 2 • Nasotracheal intubation with head positioned on a narrow headrest. Endotracheal tube sutured to columella and supported with foam to prevent pressure

on the nasal alae.

- Oral cavity cleansed with chlorhexidine gluconate mouthwash
- Preoperative intravenous antibiotic coverage for oral flora (ie, clindamycin)
- Contralateral lower extremity prepped if a free gracilis muscle flap will be utilized
- Sequential compression devices (sterile SCD on the donor leg)
- Foley catheter

Approach

- In the standard approach, the masseter nerve is explored via a preauricular incision after elevation of a cheek skin flap.
- When a limited preauricular approach is used, the neurorrhaphy is performed prior to the microvascular anastomosis to facilitate exposure.

TECHNIQUES

■ Standard Preauricular Approach

- The external auditory canal is occluded with a petrolatum gauze dressing.
- A preauricular incision with a sideburn extension is made if the superficial temporal artery and vein will be used as recipient vessels. A submandibular extension is incorporated if the facial vessel will be used.
- A skin and subcutaneous tissue flap is elevated in the preauricular, zygomatic, and buccal regions, extending the medial aspect of the dissection to the lateral border of the orbicularis oris muscle.
- A point is marked on the SMAS, 3 cm in front of the tragus and 1 cm below the zygomatic arch. This landmark reliably corresponds to the general location of the underlying masseter nerve (**TECH FIG 1A**).¹
- The operating microscope is brought onto the field to enhance visualization and microsurgical dissection is utilized to identify zygomatic branches of the facial nerve that traverse this site.
- In cases of incomplete facial paralysis, these facial nerve branches are mobilized and gently retracted to provide access to the deeper tissues. Facial nerve branches are often absent in cases of developmental paralysis. This

significantly simplifies the dissection (**TECH FIG 1B**).

- With the aid of bipolar cautery, the cephalic border of the parotid is released from its attachments to the zygomatic arch and the gland is reflected inferiorly exposing the masseteric fascia.
- A window of the masseteric fascia is excised below the zygomatic arch exposing the superficial lobe of the masseter muscle.
- A right angle clamp and bipolar cautery are now utilized to release the muscle in layers by propagating the dissection through the superficial and middle lobes of the masseter muscle (**TECH FIG 1C**).
- In the deeper portion of the dissection, an electrical stimulator set at 0.5 to 1 mA at 40 Hz is employed to help identify the masseter nerve that usually resides in the zone of maximal muscle contraction.
- Small branches of the masseter nerve are frequently encountered and can be traced in a retrograde fashion back to the main trunk.
- The main nerve trunk is usually identified resting on the superficial surface of the deep lobe of the masseter muscle approximately 1.5 cm deep to the SMAS. Once identified, the main trunk of the masseter nerve is encircled with a vessel loop and the descending branch is further mobilized with microsurgical dissection (**TECH FIG 1D**).

TECH FIG 1 • A. Skin flap elevated and location of the masseter nerve marked 3 cm in front of the tragus and 1 cm below the zygomatic arch. **B.** Regional zygomatic facial nerve branches mobilized and reflected. May be absent in cases of developmental paralysis. **C.** Cross-sectional view of masseter nerve dissection with the main nerve trunk resting on the superficial surface of the deep muscular lobe. **D.** Masseter nerve identified within the muscle. The descending branch will be mobilized and selectively transected. The ascending branch will be preserved to

prevent atrophy.

- The masseter nerve is accompanied by a sizable artery, and microvascular clips can prove beneficial in achieving hemostasis and avoiding frustrating hemorrhaging that impaired visualization.
- Once the maximal length of the descending branch has been dissected, it is selectively transected and transposed into a more superficial plane to facilitate later nerve repair. It is important to preserve the integrity of the proximal branches to prevent muscle atrophy and the development of a cosmetic deformity.
- With the aid of the operating microscope, an end-to-end microsurgical nerve repair is made in an interrupted, epineurial fashion with 10-0 nylon between the masseter nerve and the motor nerve of the free muscle flap.

■ Limited Preauricular Approach

- When a limited preauricular approach is used, the neurorrhaphy is performed prior to the microvascular anastomosis to facilitate exposure (**TECH FIG 2A**).
- **TECH FIG 3** shows an extended submandibular dissection to access the facial artery and vein for recipient vessels.

TECH FIG 2 • **A.** Preoperative markings. **B.** Skin flap elevation for limited, preauricular approach. **C.**

Superficial temporal vessels isolated. **D.** Descending masseter nerve branch isolated and transected. **E.** Nerve repair followed by microvascular anastomosis to facilitate exposure.

TECH FIG 3 • Extended submandibular dissection to access the facial artery and vein for recipient vessels.

PEARLS AND PITFALLS

Selective masseter nerve transection

- The descending branch is frequently divided and used to innervate free muscle flaps. Proximal branches are left intact to prevent muscle atrophy and development of a cosmetic deformity.

Excessive power

- Small muscle flaps should be utilized to avoid excessively powerful muscle contraction and exaggerated commissure excursion. The decreased bulk in the midface enhances the cosmetic result.

Inadequate resting tone

- Free muscle flaps innervated by the masseter nerve often produce inadequate facial tone to achieve symmetry in repose. Consider additional static support with fascia and or tendon grafts.

Patient motivation

- Selection of well motivated patients with a strong commitment to postoperative physical therapy is essential.

Facial

- Some individuals may notice significant facial motion with

motion with mastication

chewing. This is often improved by favoring the contralateral cheek region when eating.

Single-stage procedure

- Facial reanimation can be achieved in a single operative setting.

POSTOPERATIVE CARE

- The patients are maintained on a clear liquid diet for 48 hours and then transitioned to a soft mechanical diet for 4 weeks.
- Please refer to Chapter 52 for additional postoperative care after free muscle flap facial reanimation.

OUTCOMES

- Single-stage procedure
- Produces greater commissure excursion than cross face nerve grafts⁷
- More reliable motion in the older patient, as compared to cross face nerve grafts⁸
- Dense innervation permits the use of small muscle flaps with less midface bulk.
- Potential for cerebral adaptation⁹
- In longer-term follow-up, greater than 80% can make a smile without clenching and more than 50% develop an effortless smile.¹⁰

COMPLICATIONS

- Thrombosis and flap loss (rare)
- Excess commissure excursion if a large muscle flap is utilized
- Masseter muscle atrophy if the main nerve trunk is divided with development of a sharp mandibular angle
- Separation of the muscle flap from orbicularis oris with retraction into the midcheek
- Adhesion of the muscle flap to the dermis if excessively thin skin flaps are elevated
- Asymmetry in repose if additional static support is not provided
- Unwanted facial motion with mastication

51 Masseter-to-Facial Nerve Transfer

CHAPTER

Michael J. A. Klebuc

DEFINITION

- The descending branch of the masseter nerve can be transferred to selected zygomatic-buccal branches of the facial nerve (V–VII) to restore motion in the midface and perioral region.
- The V to VII nerve transfer is utilized when intracranial and/or intratemporal segments of the facial nerve are irreversibly damaged in the presence of intact distal facial nerve branches and viable muscles of facial expression.

ANATOMY

- The masseter nerve branches from the mandibular nerve and passes above the lateral pterygoid muscle where it runs through the mandibular notch to enter the substance of the masseter muscle.
- Along its intramuscular path, the main trunk liberates a series of small proximal branches and terminates in a long descending branch that courses obliquely in a posterior-anterior, proximal-distal trajectory.
- The main trunk of the masseter nerve can be identified at a point 3 cm in front of the tragus, 1 cm below the zygomatic arch, and 1.5 cm deep to the SMAS (**FIG 1**).¹
- The masseter muscle has three lobes (superficial, middle, and deep).
- The motor nerve to masseter (CN V) lies on the superficial surface of the deep lobe.²

FIG 1 • Topographic landmarks for isolation of the motor nerve branch to masseter. The main trunk is identified 3 cm in front of the tragus, 1 cm below the zygomatic arch, and 1.5 cm deep to the SMAS.

- The main trunk and descending branches contain approximately 2700 and 1550 myelinated motor fibers, respectively.^{1,3}
- The descending branch of the masseter nerve is usually selected for the V to VII transfer.
- Facial nerve (somatic motor efferent component) innervates the muscles of facial expression, auricular muscles, occipitalis, posterior belly digastric, stylohyoid, and stapedius.
- The facial nerve main trunk emerges from the skull base via the stylomastoid foramen where it can be identified coursing 1 cm deep to the tragal pointer and medial to the posterior belly of the digastric muscle.⁴
- Within the parotid gland, the facial nerve divides into a temporofacial and cervicofacial trunk.

- Distal branches exit the parotid along its anteromedial border.
- The following branches innervate the corresponding muscles of facial expression⁵:
 - Frontal branch—frontalis muscle
 - Zygomatic branches—orbicularis oculi, zygomaticus major, zygomaticus minor, levator labii superioris, levator labii superioris alaeque nasi, corrugator supercilii, procerus
 - Buccal branches—buccinator, risorius, orbicularis oris
 - Marginal mandibular branches—depressor anguli oris, depressor labii inferioris, mentalis
 - Cervical branches—platysma
- Zuker point—midway point of a line drawn from the root of the helix to the lateral commissure (**FIG 2**)⁶:

FIG 2 • The facial nerve branch supplying the zygomatic major is typically found at a point half way between the root of the helix and the lateral commissure.

- Describes the approximate location of the facial nerve branch supplying the zygomaticus major muscle.

- At this location, the zygomatic facial nerve branches coursing above and below the transverse facial artery are often selected for the V to VII transfer.

PATHOGENESIS

- Employed when intracranial and/or intratemporal segments of the facial nerve are irreversibly damaged in the presence of intact distal facial nerve branches and viable mimetic muscles.
- Commonly utilized after ablative oncologic surgery or trauma involving the brainstem and skull base.
- Etiology of facial nerve injury includes resection of acoustic neuroma, facial nerve schwannoma, cerebellopontine angle tumors, AVM, cholesteatoma, and skull base tumors. Unrecovered Bell palsy, mastoiditis, and skull base fractures are other common causes of facial nerve injury.⁷

PATIENT HISTORY AND PHYSICAL FINDINGS

- The duration of the paralysis is one of the most important pieces of information garnered from the patient's history, as the masseter-to-facial nerve transfer must be performed before the muscles of facial expression have undergone irreversible atrophy.
- The V to VII transfer is optimally employed immediately at the time of tumor extirpation yet remains a viable option up to 18 months after the onset of the paralysis.
- The patient's age is also of consequence in surgical planning. Generally, in the older patient population (greater than 55 years), the V to VII transfer is used in isolation with fascia lata grafts for additional static support. In younger patients, the V to VII transfer is often combined with cross face nerve grafts (CFNG) in a single operative setting. This is performed in an effort to create a marriage of power (V–VII) and spontaneity (CFNG).^{8,9}
- A history of diabetes, coronary artery disease, chronic obstructive pulmonary disease, smoking, underlying neurologic disorders, previous head-neck radiation, and temporal mandibular joint dysfunction should be noted and accounted.
- The patient's level of motivation and willingness to comply with postoperative physical therapy is also important to ascertain.
- On physical examination, active, forceful contraction of the masseter and temporalis muscles is confirmed by palpation.
- The face is examined for previous access incisions and signs of trauma or

injury to the muscles of facial expression.

- Dental occlusion and mouth opening are evaluated to rule out temporomandibular joint dysfunction.
- A cranial nerve examination is performed to identify additional neurologic deficits.
- The eye is examined for signs of exposure keratitis as adjunctive eye procedures may be performed with the V to VII transfer to maintain corneal health.
- A vascular examination of the lower extremities is undertaken to rule out significant peripheral vascular disease if fascia lata or sural nerve grafts are to be harvested.

IMAGING

- MRI of the brain and facial nerve
 - High-resolution multiplanar T1 and T2 images, gadolinium enhanced, fat suppressed, and internal auditory canal (IAC) protocol
 - Used to evaluate injury to the facial nerve (ie, Bell palsy, tumors, stroke)
- Computed tomography
 - 0.625 mm or thinner axial images, reconstructions in coronal plane
 - Valuable for imaging temporal bone fractures
- EMG of the masseter muscle and mimetic muscles innervated by the facial nerve
 - Look for signs of early facial nerve recovery.
 - Look for signs of reversible muscle atrophy.
 - Look for signs of coordinated activity between the mimetic muscles and the masseter.

SURGICAL MANAGEMENT

Preoperative Planning

- Smoking cessation and avoidance of nicotine
- Discontinuation of oral anticoagulants
- Facial nerve imaging as guided by the etiology of the paralysis (MRI, CT)
- EMG
 - Presence of muscle fibrillation (suggests potential, positive response to reinnervation)
 - Concomitant activation of the masseter muscle with smiling (may predict

development of an effortless smile)

Positioning

- Supine on the operating table with arms tucked
- Narrow head extension with foam or gel-filled headrest
- Nasotracheal intubation with nasal RAE endotracheal tube sutured to the columella and supported on the hair-bearing scalp with foam, silk tape, and staples (**FIG 3**)
- Oral cavity cleansed with chlorhexidine gluconate mouthwash
- Lower extremities prepped if nerve or fascia grafts are to be utilized

FIG 3 • Nasotracheal intubation with head positioned on a narrow headrest. Endotracheal tube sutured to columella and supported with foam to prevent pressure on the nasal alae.

- Sterile calf sequential compression devices
- Foley catheter

Approaches

- V to VII retrograde approach with adjacent branch preservation

- V to VII anterograde approach with distal, selective, facial nerve branch transection
- V to VII with fascia lata static suspension
- V to VII with CFNG

TECHNIQUES

■ Retrograde Masseter-to-Facial Nerve Transfer

- The anterior border of the masseter muscle is palpated and marked.
- A pretragal incision with an extension into the sideburn is now marked with a surgical pen.
- An additional point is marked half way between the root of the helix and the commissure to indicate the general location of the facial nerve branch to the zygomaticus major muscle (Zuker point).⁶
- The topographic location of the masseter nerve is also marked 3 cm in front of the tragus and 1 cm below the zygomatic arch (**TECH FIG 1A**).
- A petrolatum gauze dressing is utilized to occlude the external auditory canal.
- The subcutaneous tissues in the preauricular, zygomatic, and buccal regions are infiltrated with a 1:100 000 epinephrine, hemostatic solution (**local anesthetics should be avoided to preserve nerve stimulation**).
- The preauricular incision with the sideburn extension is made, and a skin and subcutaneous tissue flap is elevated in the preauricular, zygomatic, and buccal regions extending the medial aspect of the dissection approximated 3 cm past the medial border of the masseter muscle (**TECH FIG 1B**).
- A SMAS flap is now elevated with scissor dissection and bipolar cautery. The flap is mobilized to the anteromedial border of the parotid gland where the inferior zygomatic and buccal branches of the facial nerve are identified. The SMAS flap is released transversely along the zygomatic border and reflected to facilitate exposure.

Video p8-c051

- The operating microscope is brought onto the field to enhance visualization, and microsurgical dissection is utilized to further explore and mobilize the facial nerve branches.
- During the dissection, the transverse facial artery is often encountered. This is a useful landmark, as the zygomatic branches above and below this structure often produce an excellent smile with little activation of the orbicularis oculi (**TECH FIG 1C**).

TECH FIG 1 • A. Operative markings: preauricular incision with a possible submandibular extension (X) marks Zuker point and (asterisk) identifies the general location of the motor nerve branch to masseter. The *dashed lines* represent the anterior border of the masseter muscle and the region of skin flap elevation. **B.** Demonstrates the extent of the skin-subcutaneous flap elevation and initial SMAS flap dissection. **C.** The facial nerve branches bordering the transverse facial artery are frequently selected for transfer as they often produce an isolated smile with little or no activation of the orbicularis oculi or orbicularis oris.

- These facial nerve branches often merge into a larger common branch. This is dissected in a retrograde fashion through the parotid gland until it dives into a deep plane in the preauricular region. At this point, adequate nerve length is usually present to achieve a primary nerve repair. However, the facial nerve is left undivided until this can be confirmed.
- Once the selected facial nerves have been mobilized, attention is focused on identifying the motor nerve branch to the masseter.

Identifying the Motor Nerve Branch

- A point 3 cm in front of the tragus and 1 cm below the zygomatic arch is again marked. The masseter fascia is released from the inferior border of the zygomatic arch with the bipolar cautery exposing the superficial surface of the masseter muscle.
- A right-angle clamp and bipolar cautery are now utilized to release the muscle in layers, propagating the dissection through the superficial and middle lobes of the masseter muscle (**TECH FIG 2A**).
- In the deeper portion of the dissection, an electrical stimulator set at 0.5 to 1 mA at 40 Hz is employed to help identify the masseter nerve that usually resides in the zone of maximal muscle contraction.
- Small branches of the masseter nerve are frequently encountered and can be traced in a retrograde fashion back to the main trunk (**TECH FIG 2B**).
- Once identified, the main trunk of the masseter nerve is encircled with a vessel loop, and the descending branch is further mobilized.
- The masseter nerve is accompanied by a sizable artery, and microvascular clips can prove beneficial in achieving hemostasis and avoiding frustrating hemorrhaging and impaired visualization.
- Once the maximal length of the descending branch has been dissected, it is selectively transected and transposed into a more superficial plane to facilitate later nerve repair. It is important to preserve the integrity of the proximal branches to prevent muscle atrophy and the development of a cosmetic deformity.

TECH FIG 2 • A. The main trunk, proximal ascending branches, and descending branch of the masseter nerve are identified via an intramuscular window. **B.** Cross-sectional view of masseter nerve dissection with the main nerve trunk resting on the superficial surface of the deep muscular lobe.

Dividing the Nerve Branch

- After verifying adequate length, the previously mobilized facial nerve branch is divided. With the aid of the operating microscope, an end-to-end microsurgical nerve repair is made in an interrupted, epineurial fashion with 10-0 nylon (**TECH FIG 3**).
- The SMAS flap is now returned to its native location and secured with absorbable monofilament sutures.
- The plane of subcutaneous dissection is treated with fibrin glue, and a 10-French closed suction drain is inserted.
- A layered closure of the access incisions is now performed, and the incisions are covered with antibiotic ointment. Stickers cautioning the need to avoid pressure are applied to the cheek.
- A deep, atraumatic extubation is then coordinated with the anesthesia provider.

C

TECH FIG 3 • **A.** Microsurgical neurorrhaphy between the descending branch of the masseter nerve and selected zygomatic branches of the facial nerve. **B.** Masseter nerve location marked on SMAS 3 cm in front of the tragus and 1 cm below the zygomatic arch. **C.** Zygomatic facial nerve branches and the descending branch of the masseter nerve isolated for transfer.

■ Antegrade Masseter-to-Facial Nerve Transfer With Distal, Selective, Facial Nerve Branch Transection

- A preauricular incision with a subsideburn extension is created, and a broad based skin flap is elevated carrying the dissection 2 to 3 cm past the anterior border of the parotid gland. If additional exposure is required, a submandibular extension can be added to the original incision.
- The relatively avascular interval between the posterior border of the parotid gland and tragal cartilage (cartilaginous portion of the external auditory canal) is dissected with the aid of bipolar cautery and self-retaining Weitlaner retractors.
- The dissection is propagated deeply into the mastoid and retromandibular region. The main trunk of the facial nerve is identified exiting the skull base via the stylomastoid foramen approximately 1 cm deep to the tragal pointer and medial to the posterior belly of the digastric muscle.⁴ The main trunk of the facial nerve emerges from the skull base approximately 5 cm from the skin surface (**TECH FIG 4**). The depth of this structure is significant, and a submandibular extension of the access incision can be made to facilitate exposure, although it detracts from the overall aesthetics of the result.
- The main trunk of the facial nerve is encircled with a vessel loop and electrically stimulated to verify the absence of function. Blunt dissection with a fine right-angle clamp and bipolar cautery is then utilized to trace the nerve into the substance of the parotid gland. The nerve often transitions rapidly into a vertical course before separating into two divisions (temporofacial and cervicofacial) at the pes anserinus. The facial nerve branches are now dissected in an antegrade manner in a fashion akin to a superficial parotidectomy. The facial nerve branch mobilization is terminated approximately 1 to 2 cm from the anterior border of the parotid (**TECH FIG 4B**).
- In cases of complete facial paralysis, the main trunk of the facial nerve is transected at the stylomastoid foramen and transposed anteriorly to provide unobstructed access for the masseter nerve dissection (**TECH FIG 4C**).
- In cases of incomplete paralysis, isolation of the masseter nerve is significantly more complicated, as the main trunk of the facial nerve is left intact and the dissection must be propagated between the zygomatic branches to the eye, without injuring these structures.
- In cases of complete paralysis, the frontal branch, zygomatic branches innervating the orbicularis oculi, and the cervical branches are selectively transected to prevent development of synkinesis.

- The descending branch of the masseter nerve is now mobilized and selectively transected (as described above in the retrograde approach). An end-to-end neurorrhaphy is now created with the aid of the operating microscope and 10-0 nylon (**TECH FIG 4D-F**).
- The parotid fascia is repaired with absorbable monofilament sutures, the region of subcutaneous dissection is treated with fibrin glue, and the access incision is closed over a 10-French closed suction drain.
- “No pressure” stickers are applied to the cheek, and an atraumatic extubation is coordinated with the anesthesia provider.

TECH FIG 4 • A. Facial nerve trunk identified exiting the stylomastoid foramen approximately 1 cm below the tragal pointer. **B.** The intraparotid portion of the facial nerve dissected in a fashion analogous to a superficial parotidectomy. **C.** Facial nerve trunk selectively transected to enhance exposure and frontal, selected zygomatic, marginal mandibular and cervical branches of the facial nerve divided to prevent

synkinesis. Masseter nerve identified resting on the deep lobe of the masseter muscle. **D.** Microsurgical neurorrhaphy between the masseter and facial nerve in an end-to-end fashion utilizing the operating microscope. **E.** Clinical example of the facial nerve mobilized within the parotid gland. *Arrow* and vessel loop identify the facial nerve branches to zygomaticus major and levator anguli oris. **F.** *Arrow* identifies the descending branch of the masseter nerve coapted to facial nerve trunk with 10-0 nylon in an interrupted epineurial fashion.

■ Masseter-to-Facial Nerve Transfer With Fascia Lata Grafts

- Isolated V to VII transfers in adult patients often lack adequate resting tone.
- In elderly patients, the V to VII transfer is often combined with fascia lata grafts for provision of additional, static support.
- The fascia lata graft is harvested from a proximal, lateral thigh incision with the aid of a lighted retractor. A graft measuring approximately 15 to 17 cm in length and 3 cm in width is obtained, and the fascial defect repaired with 0 polydioxanone suture. A layered closure is performed over a 15-French closed suction drain, as the donor site is prone to seroma formation.
- The graft is frequently divided into three segments that can be used independently to support the upper lip, commissure, and lower lip.
- The grafts can be positioned in the subcutaneous plane or delivered through Bichat-fat pad via a retrozygomatic tunnel.
- Only mild overcorrection is required as the reinnervated muscles of facial expression will provide additional support, and limited stretching of the fascia lata graft will develop.

■ Masseter-to-Facial Nerve Transfer With Cross Face Nerve Grafts

- In the younger patient population, the V to VII transfer is frequently combined with cross face nerve grafts (single-stage operation) in an effort to enhance spontaneity and resting tone.⁹
- The cross face nerve grafts are performed as described in Chapter 49 and the V to VII transfer as described above.
- Electrical stimulation of the unaffected, contralateral facial nerve branches is utilized to create a functional map, and the information is extrapolated to the “electrically silent” side to guide the distal nerve repairs.
- Typically, three to four cross face nerve grafts are combined with the V to VII transfer and target the orbicularis oculi, zygomatics major, orbicularis oris, and lower lip depressors (**TECH FIG 5**).

TECH FIG 5 • Three to four cross face nerve grafts are combined with the V to VII transfer and target the orbicularis oculi, zygomatics major, orbicularis oris, and lower lip depressors.

Proximal nerve branch preservation	■ Only the descending branch of the masseter nerve should be transferred. Proximal branches are left intact to prevent irreversible atrophy and a cosmetic deformity.
Static support	■ Fascia lata grafts are frequently required in older patients as the V to VII may not create adequate resting tone.
Sialocele	■ When extensive intraparotid dissection is performed, salivary collections can develop. This is reduced with the application of fibrin glue in the subcutaneous plain and usually responds to glycopyrrolate.
Patient motivation	■ These techniques are best suited to highly motivated individuals who are strongly committed to participate in postoperative therapy.
TMJ dysfunction	■ There is a potential for exacerbation of TMJ dysfunction, and therefore one should consider an alternate technique.

POSTOPERATIVE CARE

- No surgical dressings employed; apply antibiotic ointment to incisions for 48 to 72 hours.
- Avoid pressure on the surgical site (only one thin pillow under the head).
- Avoid incentive spirometry, and encourage deep breathing.
- IV antibiotic coverage for skin organisms and anaerobic oral flora (ie, clindamycin)
- Sequential Compression Devices (SCDs) and early mobilization
- Chlorhexidine mouthwash for 5 to 7 days and then electric toothbrush
- Soft mechanical diet for 4 weeks
- Once motion develops, the patient must practice smiling in front of a mirror (visual feedback) for a minimum of 30 min/d.

OUTCOMES

- Facial tone usually starts to develop at 3 to 4 months and facial motion at 5 to 6 months.^{7,10}
- In longer-term follow-up (greater than 2 years), 75% of patients can create a smile without clenching their teeth.
- Average commissure excursion achieved is 90% of the normal side.

- Many patients fail to develop adequate resting tone. Static suspension and cross face nerve grafts are frequently employed to counteract this problem.
- Donor site problems are rare due to the duplication of function between the masseter and temporalis muscles and the selective transection of only the descending branch of the masseter nerve.¹¹

COMPLICATIONS

- Sialocele formation that usually responds to glycopyrrolate
- Otitis externa from collection of sanguineous material in the external auditory canal
- Masseter muscle atrophy and development of a sharp mandibular angle if the entire masseter nerve is transected
- Oral-ocular, synkinetic dysfunction that usually responds favorably to botulinum toxin injections and is preferable to paralytic ectropion

Pediatric Facial Reanimation Using a Functional Gracilis Muscle Transfer

52

CHAPTER

Brad M. Gandolfi, Jeffrey R. Marcus, and Michael R. Zenn

DEFINITION

- *Facial paralysis* does not describe a disease but instead the sequelae of denervation resulting from a spectrum of diseases, congenital defects, and acquired defects with a similar effect on the facial musculature.
- Facial nerve paralysis can involve the entire facial nerve distribution or only certain branches of the facial nerve. The facial nerve may be affected symmetrically or asymmetrically. The extent of the paralysis may be complete or incomplete relative to residual motor capacity.
- The pathogenesis of facial paralysis is complex and dependent on the etiology of the disease.^{1,2} That discussion is beyond the scope of this chapter but briefly can be divided into congenital and acquired facial paralysis (Table 1). An accurate diagnosis is crucial to selecting the proper surgical (or nonsurgical) intervention.
- *Facial reanimation* is a general term to describe restoration of facial movement. There are two main distinctions based on the status of native facial muscles:
 - Nerve transfers—When the denervating event is such that existing native facial musculature can be amenable to reinnervation with a functioning nerve, a nerve transfer is warranted. In this setting, the goal may be to restore multiple facial nerve targets—ie, multiple separate but coordinated movements.
 - Functional muscle transfer—In long-standing or congenital facial paralysis,

native muscles are not present to perform the function. Therefore, a transfer of functioning muscle provides reanimation. In such cases, only one facial movement, rather than multiple, is the goal of the procedure. One muscle provides one movement.

- This chapter focuses on free muscle transfer for restoration of smile in the pediatric population.

ANATOMY

Facial Nerve

- The facial nerve exits the stylomastoid foramen and enters the posterior parotid gland, dividing the gland into superficial and deep components.
- The facial nerve divides into two main branches within the parotid gland: the frontozygomatic and the cervicofacial trunks. These branches further divide before exiting the parotid gland.
- Five branches are classically described as exiting the parotid (frontal/temporal, zygomatic, buccal, marginal mandibular, and cervical). However, the branching pattern for each individual is unique, and many of the abovenamed nerves exist in multiples.³ The average number of branches exiting the parotid is 7 (**FIG 1**).
- Buccal and zygomatic branches begin to arborize and cross within and beyond the parotid, resulting in redundancy in the functional territory of these buccal-zygomatic branches.^{3,4} It is difficult to separate the activity of these branches as purely buccal or zygomatic because stimulation often results in a mixed response. Due to mixed nerve function, sacrifice of one nerve for end-to-end coaptation does not result in functional loss.
- The target for reanimation of smile is a buccal or zygomatic branch, selected based on targeted muscle stimulation. Stimulation should ideally identify a branch that produces vertical and horizontal movement of the commissure and upper lip consistent with the patient's natural smile, with minimal extraneous movement.
- Zuker point describes a relatively consistent buccal-zygomatic branch that meets the needs for facial reanimation.⁴ It is found at the center of a line drawn from the oral commissure to the helical root.

Nerve to the Masseter

- The nerve to the masseter arises as a branch of the trigeminal nerve (V3),

passing posterior to the temporalis muscle en route to the deep surface of the masseter (**FIG 2**).^{5,6}

Table 1 Causes of Facial Paralysis						
Congenital		Acquired				
Syndromic	Nonsyndromic	Traumatic	Tumor	Inflammatory	Neurodegenerative	Infectious
Developmental	Developmental	Intracranial	Benign	Bacterial	Bacterial	Bacterial
Genetic	Genetic	Extracranial	Malignant	Viral	Viral	Viral
Intrapartum	Intrapartum			Toxic	Toxic	Toxic
Idiopathic	Idiopathic			Genetic predisposition	Genetic predisposition	Genetic predisposition

FIG 1 • The anatomy of the facial nerve.

- The nerve is reliably found 3 cm anterior to the tragus, 1 cm inferior to the zygomatic arch, and 1.5 mm deep to the SMAS.^{5,6}

Gracilis Muscle

- The gracilis muscle originates along the body and inferior ramus of the pubis, just below the pubic tubercle.⁷ It runs along the medial thigh and inserts into the medial tibial condyle, immediately deep to the sartorius muscle (**FIG 3A**).
- The gracilis lies immediately posterior to the much larger adductor longus, which is easily palpated on most patients.

FIG 2 • The nerve to the masseter is found by splitting the temporalis and masseter muscles, under the zygoma. Reprinted from Borschel GH, et al. The motor nerve to the masseter muscle: an anatomic and histomorphometric study to facilitate its use in facial

reanimation. *J Plast Reconstr Aesthet Surg.*
2012;65(3):363-366, with permission from Elsevier.

FIG 3 • Gracilis muscle with the pedicle ex vivo. Note the length of obturator nerve (left side of image).

- The muscle is supplied by the medial circumflex femoral artery, a branch of the deep femoral artery. The pedicle runs underneath the adductor longus en route to the gracilis.
- The artery enters the muscle 5 to 12 cm inferior to the pubic tubercle. It is generally 1 to 2 mm in diameter and may have two or three branches at the level of the muscle (**FIG 3B**).
- The artery is accompanied by two vena comitantes.
- The artery and the accompanying vein are 5 to 6 cm when dissected to the deep femoral vessels.
- The muscle has a minor pedicle at its distal aspect that is not appropriate for microvascular transfer.
- A branch of the obturator nerve supplies the gracilis muscle. It splits from the anterior branch of the obturator behind the pectineus and runs with the branch to the adductor longus. The nerve joins the muscle from its lateral aspect, generally at a 45-degree angle to the vascular pedicle. The nerve pierces the muscle and arborizes within it.
- The gracilis muscle has a tendinous origin from the pubis, which can be included with the flap. The muscle can be 3 to 4 cm wide at the level of the pedicle, requiring some muscle splitting to avoid bulky reconstructions.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most important initial distinction in the preoperative evaluation of pediatric patients with facial paralysis is whether the condition is congenital or acquired. For those with congenital paralysis, the condition may have been apparent at birth or recognized shortly thereafter (**FIG 4**). For those with acquired paralysis, the circumstances and details of the inciting event(s) should be carefully noted. The timing of functional loss is the most critical detail.

FIG 4 • Photo taken shortly after birth, depicting a left-side congenital facial nerve paralysis.

- Functional impairment, including the following, should be noted:
 - Excessive tearing and/or dryness requiring frequent use of lubricating drops
 - Inability to close the eyes fully at night requiring the use of viscous eye lubricant
 - Oral incompetence (drooling) or speech articulation difficulties
 - Presence and extent of dental caries, which are predisposed on the affected side
- Any prior treatments should be noted as well as any progression or improvement in the condition.
- Prior medical, neurologic, or surgical history that would potentially be associated with the condition or the potential surgical treatments that may be considered should be noted.
- A focused examination of the function of the facial nerve is performed, taking care to document both static and dynamic deficiencies. The motor territory associated with each branch should be graded relative to the completeness of the paralysis. We prefer the Toronto Facial Grading System to track our progress.² If etiology of paralysis is unclear, level of injury can be elucidated using the Schirmer test, stapedius reflex test, salivary flow test, and taste examination.
- Photographs and video of the following should be included in the initial evaluation:
 - Repose
 - Brow elevation

- Eye closure (gentle)
- Eye closure (strong)
- Smile (lips together)
- Smile (natural dental display)
- Full dental display
- Pucker
- The ability to close the eyelids such that the cornea is protected must be assessed. Those who are unable to close fully and require viscous lubrication should be identified early and treated with priority ahead of smile reanimation.
- Amblyopia may be seen in as many as 50% of patients with facial nerve palsies, and thus a thorough ophthalmologic examination is warranted.¹ The eye examination should also assess for corneal pathology due to exposure.
- The presence of the facial artery should be confirmed. It is palpable in most patients regardless of age.
- The temporalis and masseter muscles should be palpated, particularly if considering the motor nerve to the masseter as a potential donor nerve. Normal strength and mass should be present.
- Syndromic associations can be seen in congenital facial paralysis and can include hemifacial microsomia, Mobius syndrome, and Poland syndrome among others. Therefore, the examination should include an evaluation of the facial bones (orbits, zygoma, maxilla, and mandible), soft tissues, and ear. Mobius syndrome includes the presence of a cranial nerve VI deficit and can also be associated with a Poland deformity and congenital hand anomalies. Thus, cranial nerves VI, VII, IX, X, and XII should be evaluated for disability.

IMAGING

- For candidate patients with long-standing or congenital paralysis, a radiographic workup is generally unnecessary. For those with associated congenital anomalies, such as craniofacial microsomia, craniofacial CT may be valuable for the comprehensive workup.
- In cases of recently acquired facial paralysis, an EMG may be useful to establish a baseline, demonstrate improvement, or predict recovery. In congenital or long-standing cases, EMG does not provide information that contributes to treatment planning and therefore is not necessary.

NONOPERATIVE MANAGEMENT

- Nonoperative management plays an important role in partial paralysis. A facial

rehabilitation specialist may be able to obtain a more symmetric smile by strengthening weaker muscles and de-emphasizing stronger, more active muscles. Such treatment requires participation of the child.

- In certain instances of incomplete paralysis, neurotoxins can be used on the unaffected side as an adjunct to obtain symmetry.
- Long-standing, complete, and near-complete paralysis in the pediatric population generally requires surgical management.

SURGICAL MANAGEMENT

- For the pediatric patient with congenital or long-standing complete paralysis affecting smile, our preferred treatment is microvascular free functional gracilis transfer. Using the gracilis, we can obtain satisfactory, and often outstanding, static and dynamic symmetry of smile.
- For unilateral facial paralysis, we prefer to use a branch of the facial nerve from the contralateral (functional) side to power the gracilis by way of a cross face nerve graft (CFNG). This allows a spontaneous, emotion-driven smile.
- In cases of bilateral facial paralysis, the nerve to the masseter is coapted to the obturator nerve, powering the functional gracilis. This nerve is powerful, is located in the field of dissection, and does not cause a functional deficit. Although jaw clenching (masseter activation) is required to stimulate activity in the transferred muscle, with postoperative psychomotor training, the patient can learn to use this muscle spontaneously. However, in contrast to CN VII (CFNG), the masseter nerve—which arises from CN V—lacks baseline tone. Therefore, even a strong smile powered by the masseter nerve will lack baseline tone in repose and therefore will potentially still be associated with repose asymmetry including facial shift.

Preoperative Planning

- As with any operation, the patient and parents should be thoroughly informed of risks, benefits, and expected outcomes of the procedure. Free flaps in any population may be lengthy in duration and carry a rare but present risk for early failure. Even when technically successful, achievement of a long-term symmetric smile cannot be guaranteed.
- Families must be briefed on the nature of nerve coaptations, timing of functional results, and postoperative care necessary. In general, the timing of nerve regeneration is as follows:
 - Two-stage repair:

- Cross face nerve graft: 6 to 9 months
 - In older children, a Tinel sign may be followed. In younger children, it may not be elicited.
- Free gracilis transfer: 6 to 12 months
- Nerve to masseter: 2 to 4 months
- Lack of activity (visible or palpable) beyond the later time limits suggests a poor prognosis relative to success of the procedure.
- Preoperatively, the patient is asked to smile, and the vectors of commissure and upper lip elevation are marked on the normal side (if present). These will be used to guide the reconstruction. It is important to do this with the patient in the upright position. Care must be taken not to wash these marks off during the procedure.
- In cases of bilateral paralysis, two sequential single-stage procedures using the nerve to masseter are performed. The vectors of desired pull to obtain a smile are also marked in these patients, guided by the typical appearance and location of the nasolabial fold.
- Given the substantial recovery process required, it is helpful to schedule the muscle transfer in the summer for school-aged children.
- As noted, a Tinel sign may or may not be present over the distal aspect of the CFNG. In the event that the Tinel sign cannot be elicited, intraoperative frozen section of the CFNG may confirm a normal fascicular pattern, thus confirming nerve regeneration and readiness for free muscle transfer.
- The functional muscle transfer of the gracilis is best accomplished with two surgical teams, minimizing anesthetic time and allowing the procedure to be accomplished in a safe and efficient manner. One team focuses on the recipient site preparation, whereas the other harvests the gracilis muscle and prepares it for transfer.

Positioning

- Stage 1 of two-stage procedure (CFNG):
 - A discussion with anesthesia team is important. The following needs must be conveyed:
 - No paralytic agents after induction
 - Choice of endotracheal tube and method of stabilization should not distort facial features or interfere with assessment of stimulation during surgery. The authors prefer nasal or oral RAE for stage 1 procedures.

- The bed is turned 90 degrees to allow all surgeons access to the field. The circuit must be long enough to accommodate the positioning.
- Corneal protection and lubrication must be provided and accommodated at each step of the operation.
- The surgery starts in the prone position, with harvest of the sural nerve.
- Once the nerve is harvested and the leg incisions closed, the patient is turned supine for the facial nerve dissection and nerve coaptation.
- Stage 2 of two-stage procedure or single-stage gracilis transfer (CNV masseter):
 - The patient is placed in the supine position.
 - The bed is positioned so the anesthesiologist is at the ipsilateral hip (turned 90 degrees), which allows both teams to operate freely.
 - For gracilis harvest, the legs are placed in a frog-leg position, with the hips and knees gently flexed. The ipsilateral gracilis is used for the following reasons:
 - The direction of the nerve and vascular pedicle are appropriate to allow muscle to be positioned in line with the facial artery and nerve and with maximal available obturator nerve length.
 - Two teams may operate simultaneously without interference.

Approach

- First stage (CFNG):
 - The sural nerve is harvested first. We prefer stair-step incisions (3) with a lighted retractor and direct visualization of the nerve during dissection. The proximal portion of the sural nerve is preferred due to size match and limited branching.
 - The facial nerve exploration is accomplished through a preauricular (face-lift) incision with a 3- to 5-cm extension along the mandibular angle to facilitate exposure (**FIG 5A**).
- The gracilis harvest is accomplished through a 10-cm incision placed over the medial aspect of the upper thigh.
 - The incision is placed on a line drawn from the inferior ramus of the pubis to the medial tibial condyle, centered approximately 10 cm below the pubic tubercle (**FIG 5B**).
- Recipient site (paralyzed face) and nerve to masseter
 - Similar to first-stage CFNG, the incision follows a preauricular face-lift

design with an extension 3 to 5 cm along the angle of the mandible.

- The incision stops 2 cm anterior to the palpable facial artery, which limits the length of incision while providing adequate microsurgery exposure.

FIG 5 • **A.** Incision pattern for a first-stage cross face nerve graft. **B.** The incision for the gracilis is centered on the presumed location of the pedicle on the medial thigh.

TECHNIQUES

Video p8-c052

■ Cross Face Nerve Graft

- The field is copiously infiltrated with a dilute solution of epinephrine (without any local anesthetic). This decreases blood loss, enhancing visibility, and facilitates the skin flap elevation.
- A modified face-lift–style incision is made on the normal (nonparalyzed) side as described above (see **FIG 5A**).
- Sharp dissection proceeds in a superficial plane until the border of the parotid is reached. Skin hooks are used for retraction.
- Once the border of the parotid is reached, the SMAS is incised, and the dissection continues in the sub-SMAS plane (**TECH FIG 1A**).
- The branches of the facial nerve are identified exiting the parotid with the help of a nerve stimulator (**TECH FIG 1B**).
- A proper donor nerve is identified. The donor nerve should supply the zygomaticus muscles and the levator labii. Nerves that simultaneously supply portions of the orbicularis should be avoided, if possible. The goal is to find a nerve that produces the patient's natural smile in relative isolation. The candidate nerves are then followed distally. Stimulation of two or three candidate branches ensures that enough redundancy exists to preclude functional loss with sacrifice of the ideal donor selection.

TECH FIG 1 • **A.** Incision of SMAS to enable donor nerve dissection. **B.** Nerve branches are identified on

the nonparalyzed side. **C.** The sural nerve is passed through a preperiosteal tunnel across the maxilla using stepped incisions. Tunneling is facilitated by securing the end of the nerve to a vessel loupe and sliding the loupe through the tunnel.

- A preperiosteal tunnel is then created from the medial extent of the dissection plane to the superior buccal sulcus. A small incision is made at the level of the contralateral canine to aide in the dissection.
- A vessel loop is then passed from the buccal sulcus incision into the edge of the face-lift dissection site (**TECH FIG 1C**).
- The sural nerve is harvested at this time.
- The nerve graft is reversed and then secured to the end of the vessel loop. The vessel loop is then pulled back through the subcutaneous tunnel, delivering the distal end of the nerve graft to the upper buccal sulcus atraumatically.
- The distal end of the graft is tagged with a hemoclip and secured to the periosteum lateral to the canine with a 4-0 nylon suture. This aids in identification at the second stage.
- The upper buccal sulcus incision is then closed.
- The proximal nerve graft is coapted to the donor facial nerve end to end under the surgical microscope.
- The cheek flap is then closed using 4-0 Vicryl dermal sutures, followed by 4-0 nylon skin suture. A short Penrose drain segment is placed for 24 hours.
- No compressive dressings or head wraps are used.

■ Identification of Nerve to Masseter

- The nerve to the masseter is identified after cheek flap elevation (described below in the gracilis muscle inset).
- An incision is made in the SMAS anterior to the temporomandibular joint, parallel to the zygomatic arch and just below the arch (**TECH FIG 2A**).
- Dissection proceeds through the superficial and intermediate muscle bellies of the masseter, and a nerve crossing obliquely from zygomatic arch to commissure is sought. The nerve can be found 3 cm anterior to the helical

root and 1 cm below the arch. A nerve stimulator may be used to help identify the nerve (**TECH FIG 2B**).

- The nerve is traced to its entrance into the undersurface of the masseter, where it is transected and transposed superficially (**TECH FIG 2C**).
- Any excess obturator nerve is trimmed prior to coaptation to the masseteric nerve to decrease reinnervation time.

TECH FIG 2 • A. The incision to find the nerve to the masseter is anterior to the TMJ, just below the arch. **B.** The nerve to the masseter is identified. **C.** The nerve is superficially translocated and coapted to the obturator nerve.

■ Recipient Site Preparation

- The field is copiously infiltrated with a dilute solution of epinephrine (without any local anesthetic). This decreases blood loss, enhancing visibility, and facilitates the skin flap elevation (**TECH FIG 3A**).
- A pretrichial, retrotragal incision is made on the paralyzed face. The incision follows the pattern of a basic face-lift incision with an extension inferiorly that allows access to the facial vessels (**TECH FIG 3B**).
- The area from the zygomatic arch to the mandible is elevated in a sub-SMAS plane toward the oral commissure.
- The buccal fat pad is resected to decrease cheek bulk in anticipation of muscle placement (**TECH FIG 3C**). Additionally, deep fat of the cheek is excised as necessary or available.
- The facial vessels are identified and isolated. The vessels are dissected to the level of the commissure to provide length and different diameter choices for

anastomosis (**TECH FIG 3D**).

- Using preoperative vector marks as guides, three to four no. 2 Vicryl inset sutures are placed internally in the upper lip, commissure, and occasionally at the lower lip. One suture is always placed at the commissure.
- Generally, two sutures are placed for the upper lip.
- Depth of suture placement is key, as too shallow a bite will cause lip eversion and too deep lip inversion.
- If orbicularis muscle is present, sutures can be placed through the muscle. In many cases, no muscle is present, and sutures are placed in the submucosa (**TECH FIG 3E**).
- As sutures are placed, traction is placed on the suture to replicate smile. Suture placement is modified until the vectors of pull and the nasolabial fold mimics the anticipated smile (**TECH FIG 3F**).

TECH FIG 3 • A. The dissection plane is copiously injected with dilute epinephrine. The incision for the gracilis recipient site on the face mimics a face-lift with an inferomedial extension along the mandible to

access the facial vessels. **B.** The gracilis muscle is measured for size and cut to length in situ. **C.** The ipsilateral buccal fat pad is resected to decrease the bulk deformity of the gracilis muscle. **D.** The facial vessels are identified at the border of the mandible. **E.** A series of sutures are placed at commissure in preparation for securing the muscle. **F.** The location of the commissure sutures is checked by placing traction on them and assessing the smile produced.

Determination of the Length of Muscle Needed for the Reconstruction

- This is done with slight traction applied to the inset sutures such that a slight smile is created.
- For purposes of semantics, we refer to the distal inset at the commissure as the insertion and the proximal inset along the zygoma as the origin.
- The muscle is positioned along the proposed vector of the smile—a reflection of the same vector estimated and drawn on the normal side.
- The distances from the commissure to the proposed medial and lateral points of origin along the zygoma are determined (**TECH FIG 4A**).
 - The distance along the medial point of origin is shorter than that to the lateral point of origin (**TECH FIG 4B**).
- The muscle is taken at the greater length, with an additional 2 cm of length added (1 cm per side) to accommodate a row of sutures at each end. These help prevent pull-through of the subsequent inset sutures. The muscle is then cut on a bias at the proximal end to account for the medial/lateral length discrepancy.
- If pedicle position and required muscle length are ideal, the proximal tendinous portion of the gracilis may be used at the inset origin.
- Once the segmental length is determined, it must be properly centered over the pedicle.
- Three measurements must be made:
 - Total length of muscle (described above, generally around 8 cm)
 - Length of muscle proximal to the facial vessels (approximately 5 cm)
 - Length of muscle distal to the facial vessels (approximately 3 cm)

- In this way, the dimensions can be transferred to the donor site.
- The dimensions are conveyed to the donor site surgical team.

TECH FIG 4 • A. Measurements are taken from the proposed origin to the insertion of the gracilis in preparation for harvest. **B.** The gracilis muscle measurements are measured precisely using the proposed origins and insertions and their relation to the facial vessels. Most times, the anterior border of the muscle (measurement *c* in the diagram) will be shorter than the posterior border of the muscle (measurement *a*) because the origin is secured parallel to the zygoma. Measurement *b* is the length of the gracilis caudal to the vessel insertion.

■ Gracilis Muscle Harvest

- The patient is placed in the supine position. The hip and knees are slightly flexed (frog-leg position).

- The course of the gracilis muscle is marked out on the patient using anatomic landmarks as guides, and an incision is made above the course of the gracilis as described above (see **FIG 5B**).
- The incision is taken straight down toward the adductor longus. The saphenous vein will be encountered and preserved if possible.
- The adductor longus fascia is incised (**TECH FIG 5A**).
- The pedicle is identified approximately 5 to 10 cm below the pubic tubercle. It can be identified by its course: it travels below the adductor longus, entering the muscle at a 90-degree angle, at the posterolateral aspect of the muscle (**TECH FIG 5B**).
- The obturator nerve is identified as the pedicle enters the muscle, at a 45-degree angle to the muscle belly.
- The pedicle and nerve are traced under the adductor longus muscle to obtain the most length and size possible. A lighted retractor facilitates this dissection.
- A neurolysis is done to obtain greater length on the nerve pedicle. This can be taken back to the anterior and posterior division of the obturator nerve (**TECH FIG 5C**).
- Distal minor pedicles of the gracilis are ligated, and the muscle is isolated on all sides.

TECH FIG 5 • A. The adductor longus fascia (marked in *blue*) is incised to reveal the gracilis pedicle. **B.** The gracilis pedicle (*blue arrow*) and obturator nerve

(*yellow arrow*) in situ below the adductor longus. **C.** The dissection of the obturator nerve (seen over the WECK-CEL) extends under the adductor longus to its branch point. **D.** The gracilis muscle is split longitudinally to decrease bulk. **E.** The length of gracilis to be used is measured, while the muscle is still in situ. **F.** Mattress sutures are placed on the edges of the gracilis to prevent suture pull-through.

- Once isolated, a nerve stimulator is used to assess the contractile units of the muscle. The gracilis can usually be split into medial and lateral components (**TECH FIG 5D**).
 - This split occurs along a natural cleavage plane. Spanning vessels between the muscle segments should be preserved until nerve contraction has been tested.
 - The nerve is stimulated, and the best contractile segment is prepared for transfer.
 - In general, no more than one-third to one-half of the muscle is required for transfer, depending on the size of the child and muscle. Any muscle not harvested is left in situ.
- The length of the gracilis needed is then determined using measurements obtained from the recipient site (described above).
 - A total length measurement (a + b), length proximal to the pedicle (a), and length distal to the pedicle (b) will be relayed.
 - An additional 1 cm is added to each side to allow for a layer of bolster sutures to be placed at either end (**TECH FIG 5E**).
- A row of mattress sutures of 0-0 Vicryl are placed 1 cm from each end of the muscle to prevent suture pull-through (**TECH FIG 5F**).
- The proximal and distal muscle bellies are severed using bipolar electrocautery.
- Once the recipient site is ready, a heparin bolus is given. After 10 minutes, the vascular pedicle is clipped, and the muscle is transferred to the face.

■ Gracilis Muscle Inset

- The orientation of the muscle is then determined with consideration of microvascular anastomosis and the nerve coaptation.
- The previously placed inset sutures are then placed in the gracilis, just central on the gracilis to the row of mattress sutures. The muscle is then parachuted into position at the commissure (**TECH FIG 6A**).
- The obturator nerve is then passed through a previously created tunnel to the upper lip (if using a CFNG) or placed in position to coapt to the nerve to the masseter.
- The muscle is then temporarily placed and secured in its final inset position in preparation for a tension-free anastomosis that will not change after the final muscle inset.
- The microvascular anastomosis is then performed, generally vein before artery.
- The epineural nerve coaptation is performed. The buccal sulcus incision is closed at this time.
- The inset origin of the muscle is secured to the deep tissues and periosteum of the zygoma using mattress sutures of no. 1 Vicryl again behind the row of mattress sutures on the gracilis. The muscle should be spread over the inset origin to prevent excess bulk (**TECH FIG 6B**).
- When the muscle is inset, proper tension must be set. If the measurements have been properly made, the resting position will appear as a slight (20%–30% of max) smile.
- A Penrose drain is placed behind the ear by way of a separate stab wound.
- The cheek flap is closed using 4-0 Vicryl sutures in the dermis and a 5-0 Monocryl plus skin closure (**TECH FIG 6C**).

TECH FIG 6 • **A.** The gracilis muscle is parachuted into position at the commissure. **B.** The gracilis in the

final position. **C.** The skin is closed and the area drained with a Penrose drain.

PEARLS AND PITFALLS

Donor nerve evaluation

- Selection of an appropriate donor nerve for the CFNG is crucial to the overall success of the operation.
- The donor nerve should supply the zygomaticus muscles and the levator anguli oris, with minimal (if any) contributions to the orbicularis oris.
- The donor nerve branch taken must have redundancy with other nearby branches and therefore can (and should) be divided relatively proximally. This should be determined with a nerve stimulator to avoid any donor-site weakness.

Muscle inset

- An incorrectly inset muscle is nearly impossible to correct. Unfortunately, this may not be noticed until the muscle starts to function, months after the initial procedure. Care must be taken to avoid potential issues by concentrating on the following:
- Determine the desired vector of pull, and focus on adequate vertical orientation during inset.
- Use a row of mattress sutures to prevent pull-through.
- Avoid excess bulk by splitting the muscle in situ before transfer and by removing buccal fat.
- The muscle should be inset with tension to simulate 20%–30% of a natural smile.
- Avoid excess bulk by coursing the muscle posterior to the malar eminence and fanning the muscle out in the temple area.

Inset insertion suture placement

- Preoperative smile vector analysis is key to creating a pleasing smile and should be done in the upright position in the holding area.
- Time and care should be taken to place each suture in the appropriate position on the upper lip and commissure, avoiding inversion, eversion, and dimpling.
- A symmetric nasolabial fold should be created.

Gracilis harvest

- Identification of the gracilis is best done by visualizing the obturator nerve and the medial femoral circumflex vessels traversing underneath the adductor longus muscle en route to the medial aspect of the

gracilis.

- The pedicle size can be small but can be followed below the adductor longus to its origin on the profunda for additional length and diameter.
- The pedicle is best found by scoring the fascia of the adductor longus exposing the space below the adductor that contains the medial femoral vessels and obturator nerve.
- Donor site seromas are less common in facial reanimation than when the gracilis is used in breast reconstruction but still warrant placement of a drain.
- Lidocaine should not be used as a vasodilator during this portion of the procedure to avoid any effects on nerve stimulation. Papaverine is preferred.

POSTOPERATIVE CARE

- Free muscle transfers are monitored via implantable Doppler probes. Postoperative flap checks are performed on an hourly basis for 2 days, followed by every 4 hours for the next 2 days.
- Our postoperative management follows a gradual increase in activity:
 - Bed rest for 1 day
 - Gradual and slow mobilization thereafter
- No pressure on the operated side of the face for 6 weeks
- Perioperative antibiotics are given.
- Signs of reinnervation are followed in the clinic and can generally be expected at 2 to 4 months when the nerve to the masseter is used and 6 to 12 months when a CFNG is used.
- Once reinnervation is noted on examination, therapy is started. Patients work with therapists specifically trained in facial reanimation rehabilitation. We believe this to be critical to success.
- Exercises done in front of a mirror are useful to provide a feedback mechanism and improve symmetry. This should be done 2 or 3 times a day for 4 to 5 minutes at a time.
- Therapy should be continued for a period of 6 months.

OUTCOMES

- The goal of a functional gracilis transfer is smile recreation using a single vector pull of the muscle. Thus, limitations exist. A pure symmetric smile is a lofty goal, but with attention to detail and therapy, dramatic results can be

obtained (**FIG 6**).

- Studies have shown improved speech outcomes in patients with Mobius syndrome after undergoing bilateral gracilis transfers.

COMPLICATIONS

- Garcia et al. in a pooled data analysis reported a complication rate of 9.6%.⁷
- Complications included the following:
 - Postoperative hematoma (3.6%)
 - Infection (3.5%)
 - Vascular compromise (1.4%)
 - Salivary leak (1%)
 - Seroma (0.4%)
- Long-term failure of the muscle to reinnervate was reported at 1.8%

FIG 6 • Preoperative and 2-year postoperative pictures of the patient in **FIG 4**, who underwent a two-stage free gracilis transfer for a congenital facial nerve palsy.

DEFINITION

- Neurotrophic keratopathy is a degenerative corneal disease caused by impairment of corneal innervation.¹
- Corneal neurotization involves using functioning sensory nerves from elsewhere on the face as donor nerves to reinnervate the cornea and restore corneal sensation and improve ocular surface health.

ANATOMY

- The cornea is the most densely innervated part of the body.^{1,2}
- Corneal innervation derives from the ophthalmic branch (V1) of the trigeminal nerve (CN V).³
- Lesions may occur anywhere along the course of the corneal innervation pathway including the pons, the trigeminal (gasserian) ganglion, the ophthalmic branch, the nasociliary nerves, and the long ciliary nerves.
- Despite corneal nerve density, the cornea is supplied by relatively few trigeminal neurons as a single neuron may support hundreds of individual nerve endings.⁴⁻⁶
- The corneal innervation is divided into three networks: stromal, sub-basal, and epithelial.^{7,8}

PATHOGENESIS

- Corneal sensation is a necessary component of reflexive tearing and blinking, which prevent corneal injury.
- Pain ordinarily would prompt patients to seek appropriate treatment after corneal injuries; however, an insensate cornea leaves patients unaware of their

corneal injury.

- Repetitive corneal epithelial injury and ulceration cause corneal scarring and vision loss.^{9–11}
- Corneal nerves also contain neuromediators that promote corneal epithelial maintenance and repair.^{3,11}
- Immediately following corneal denervation, animal models show decreases in epithelial cell vitality and mitosis, resulting in thinning, breakdown, and ulceration of the corneal epithelium.^{12–15}

NATURAL HISTORY

- Neurotrophic keratopathy is one of the most difficult ocular diseases to treat.¹
- Prognosis is dependent on the severity of corneal hypoesthesia and the presence of other concomitant ocular disorders such as dry eye disease, exposure keratopathy, and corneal limbal stem cell deficiency.
- Patients require lifelong treatment and even with optimal management many develop vision loss and blindness in the affected eye.
- Inflammation and repeated corneal injury may also result in neovascularization of the cornea, further impeding vision.

PATIENT HISTORY AND FINDINGS

- Patients typically present with persistent asymptomatic corneal epithelial defects.
- Neurotrophic keratopathy is classified into three stages depending on clinical findings based on the Mackie classification¹:
 - Stage 1: epithelial irregularity with punctate keratopathy and minimal stromal scarring.
 - Stage 2: epithelial ulceration surrounded by a rim of loose epithelium +/- stromal swelling.
 - Stage 3: corneal ulceration involving the stroma with risk of corneal perforation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Diagnosis is based on clinical findings and a patient history of corneal hypoesthesia or anesthesia with delayed healing and persistence of corneal epithelial defects.^{16,17}
- Slit lamp: identifies corneal epithelial abnormalities, including diffuse staining with fluorescein, epithelial sloughing, and stromal neovascularization.

- Corneal esthesiometry: measures corneal sensation. This can be performed with a Cochet-Bonnet aesthesiometer (Luneau, France) by a skilled ophthalmologist.
- Schirmer test: used to diagnose concomitant dry eye disease, when needed.
- In vivo corneal confocal microscopy (IVCCM): documents the absence of corneal nerve fibers.

DIFFERENTIAL DIAGNOSIS

- Hallmark for diagnosis is the presence of a corneal ulcer and the absence of corneal sensation.
- Possible etiologies of corneal anesthesia and hypoesthesia are as follows:^{9,16}
 - Viral infection (herpes simplex and zoster keratoconjunctivitis)
 - Chemical burns
 - Physical injury to the trigeminal innervation (such as intracranial surgery)
 - Corneal surgery
 - Diabetes
 - Leprosy
 - Topical anesthetic abuse
 - Congenital (such as trigeminal agenesis, cerebellar hypoplasia, brainstem hypoplasia)
- Certain disease may also exacerbate neurotrophic keratopathy:
 - Dry eye disease
 - Exposure keratopathy; facial nerve paralysis
 - Corneal limbal stem cell deficiency

NONOPERATIVE MANAGEMENT

- The goals of treatment are to prevent corneal ulceration and promote epithelial healing when ulcerations occur.^{1,16,17}
 - Preservative-free topical artificial tears
 - Punctal occlusion
 - Therapeutic contact lenses (eg, the “Boston lens”)
 - Topical antimicrobials
 - Protective tarsorrhaphy
- If a corneal perforation is suspected, then cyanoacrylate glue or keratoplasty (cornea transplant) may be indicated.
- Exacerbating conditions, such as exposure keratopathy and limbal stem cell deficiency, should be treated.

- Experimental treatments for persistent ulcerations include topical IGF-1, substance P, or nerve growth factor (NGF).^{18–21}

SURGICAL MANAGEMENT

- Surgical management to restore corneal sensation in patients with corneal anesthesia or hypoesthesia has been described.^{22–24}
- Samii first described a surgical technique to reinnervate the cornea using an intracranial approach through an osteoplastic frontal craniotomy to guide regenerating axons directly into the ophthalmic nerve using a long sural nerve graft and the occipital nerve as donor.
- Avoiding an intracranial approach, Terzis²² described a technique using the peripheral nervous system to reinnervate the cornea by directly transferring the supraorbital and supratrochlear nerves to neurotize the cornea.
 - This technique necessitates a coronal incision and extensive dissection to access the supratrochlear and supraorbital nerves distally.
- This technique was then modified by Borschel, Ali, and Zuker,^{23,24} who were able to avoid a coronal incision by guiding axons from the proximal supratrochlear nerve into the anesthetic cornea via a sural nerve graft.
 - This technique uses two small supraorbital incisions.
 - This approach is described in detail in this chapter.

Preoperative Planning

- Thorough facial sensory nerve examination and mapping must be done in order to identify potential donor nerves for reconstruction. The authors use an occupational therapist and Semmes-Weinstein monofilaments to document facial sensation.
- All patients should be evaluated by an ophthalmologist to document visual acuity, overall ocular health, and corneal sensation using Cochet-Bonnet aesthesiometry.

Positioning

- The patient is placed in the supine position on the operating table, and the entire face is prepped and draped (**FIG 1**).
- The leg to be used for sural nerve harvest is also prepped and draped.

FIG 1 • We prefer to operate from the head of the bed with the patient in the supine position. Even with a thorough sensory examination documenting normal sensation in the contralateral face, we have found the donor supratrochlear or supraorbital nerves to be insufficiently large enough for coaptation on occasion. For this reason, we prep the patient's entire face in case we use the infraorbital nerve as a donor.

TECHNIQUES

■ Sural Nerve Harvest

- This can be performed using the surgeon's preference. We prefer using a nerve stripper device that permits harvesting of the proximal tibial component of the sural nerve, which usually provides a branch-free graft of sufficient length.

Identification of the Contralateral Supratrochlear Nerve

- Any functioning sensory nerve in the face can be used for corneal neurotization.
- Many patients have hemifacial sensory deficits associated with neurotrophic keratopathy. Our preferred technique is to use the contralateral supratrochlear nerve as a donor. If the ipsilateral supratrochlear or supraorbital nerves are normal and available, they may be used instead of the contralateral nerves.
- Two- to three-centimeter supraorbital incisions are made on the medial lower border of the eyebrows over each eye (**TECH FIG 1A**).
- The donor supratrochlear or supraorbital nerve is then identified through this incision on the donor side (**TECH FIG 1B**).
- The supratrochlear nerve is identified deep to the origin of the frontalis muscle, on the surface of the corrugator supercilii muscle traveling cephalad from the supratrochlear notch.
- The supratrochlear notch can often be palpated to guide dissection.
- Some supratrochlear nerves divide distal to the notch. Both branches can be incorporated as donors.

Tunneling of the Sural Nerve Graft to the Affected Cornea

- Once the supratrochlear or supraorbital nerve has been identified, the contralateral incision over the affected eye is deepened to the level of the subcutaneous tissue.
- A fine hemostat is used to bluntly dissect a subcutaneous plane between the two incisions to provide a passage for the sural nerve graft.
- With the distal portion of the hemostat through the incision on the affected eyelid, the distal end of the sural nerve graft is grasped and pulled through the subcutaneous pocket so that the nerve graft is traversing the incisions, reversing the direction of the nerve graft for coaptation.
- A superonasal perilimbal incision is made in the conjunctiva using blunt scissors, and a small pocket is made in the potential space between the sclera and Tenon capsule (**TECH FIG 2A**).

TECH FIG 1 • A. We palpate the supratrochlear notch to mark two incisions over the ipsilateral and contralateral supratrochlear nerves. As most patients with corneal anesthesia have hemifacial sensory abnormalities, we most frequently use the contralateral supratrochlear nerve as a donor sensory nerve for corneal neurotization. **B.** The supratrochlear nerve is identified below the level of the frontalis muscle at the location of the supratrochlear notch and is secured with vessel loop.

TECH FIG 2 • A. Once the sural nerve graft has been tunneled to the ipsilateral supraorbital incision, an incision is made into the perilimbal conjunctiva and a potential space is expanded between the conjunctiva and sclera. This permits the Wright needle to be passed from the perilimbal conjunctiva to the

ipsilateral supraorbital skin incision. **B.** The Wright needle is passed from the perilimbal conjunctival incision into the ipsilateral supraorbital skin incision. The sural nerve graft is then placed within the eye of the needle, tunneling the sural nerve graft into the orbit as the needle is withdrawn through the perilimbal conjunctival incision.

- A Wright needle (curved ophthalmologic trocar with eyelet) is then used to pass the sural nerve graft from the supraorbital incision over the affected eye, below the conjunctiva and Tenon capsule, to be delivered to the perilimbal incision (**TECH FIG 2B**).

Dissection of the Sural Nerve Fascicles

- Under the operating microscope and on the surface of the affected eye, the sural nerve graft is divided into separate fascicles so that they may be evenly distributed around the eye to reinnervate the cornea (**TECH FIG 3A**).
- We aim to produce three to four fascicles from the sural nerve graft; however, in many patients, we have used only two fascicles, with good results.
- The fascicles are then distributed around the cornea to evenly distribute the location of regenerating axons into the cornea (**TECH FIG 3B**).

Tunneling of Fascicles Into the Corneal Stroma

- Separate perilimbal incisions are then made for each of the fascicles, and again a small perilimbal pocket is made between the sclera and Tenon capsule. Each fascicle is then tunneled below the conjunctiva into these incisions to lie adjacent to the cornea.
- A corneal scalpel blade is used to make a small scleral tunnel incision 1.0 to 1.5 mm from the limbus and approximately 1.5 mm wide (about twice the width of the fascicle) into the clear peripheral cornea so that each fascicle can be tunneled directly into the cornea (**TECH FIG 4A**).
- The nerve graft fascicle is then gently placed directly into the stromal pocket (**TECH FIG 4B**), and 10-0 absorbable (Vicryl) stitch is placed through the sclera and the epineurium of the fascicle to keep the fascicle in place.
- This is then done for each of the fascicles individually.

- Each of the perilimbal conjunctival incisions are then closed with 10-0 absorbable stitch (**TECH FIG 4C**) being careful to avoid any exposure of the fascicles.

TECH FIG 3 • A. Once overlaying the cornea, the sural nerve graft is dissected into separate fascicles. **B.** Once divided into separate fascicles, these are distributed evenly around the cornea. In our experience, there are a variable number of fascicles in the sural nerve. We aim to have at least two fascicles, with a maximum of four when available. Each fascicle is then tunneled below the level of the conjunctiva through perilimbal incisions to surround the eye.

TECH FIG 4 • A. Through each perlimbal incision, an ophthalmic scalpel is used to make a pocket within the corneal stroma. **B.** Once the stromal pocket has been made, the fascicle is tunneled directly into the corneal stroma using forceps. In the image, the distal portion of the sural nerve graft can be seen protruding into the corneal stroma. Each fascicle is sutured into place proximal to the stromal pocket using 10-0 absorbable sutures. **C.** After the sural nerve fascicle has been tunneled into the corneal stroma and secured to the sclera with a 10-0 stitch, the perlimbal conjunctival incision is sutured closed.

- A limbal incision and tunneling the nerve fascicles directly into the corneal stroma may significantly improve nerve regrowth as the limbus may act as a barrier to corneal nerve ingrowth.
- The affected eye is then closed with a temporary central tarsorrhaphy suture

to protect the corneal surface after surgery, and this is left in place for 1 to 2 weeks.

- If a permanent lateral tarsorrhaphy has not been performed previously, it can be done at this step.

Nerve Coaptation

- As the final step, the distal portion of the sural nerve graft is coapted to the supratrochlear nerve in an end-to-end fashion with 10-0 nylon suture or fibrin glue (**TECH FIG 5**) or both glue and sutures, depending on surgeon preference.
- The supraorbital incisions are closed with a 6-0 subcuticular Monocryl stitch.

TECH FIG 5 • Once all conjunctival incisions have been closed, the distal portion of the sural nerve graft is coapted to the proximal stump of the transected supratrochlear nerve. We have also done side-to-end repair; however, we prefer this technique as we have found the donor site morbidity to be minimal and end-to-end repair recruits a greater number of donor sensory axons.

PEARLS AND PITFALLS

Preoperative considerations

- A thorough sensory examination is necessary prior to the operation to identify normal functioning donor nerves.

Acquired vs congenital cases

- Acquired cases usually have straightforward neuroanatomy.
- Congenital cases often have aberrant anatomy.
 - These cases may have complete absence of any supratrochlear or supraorbital nerves despite intact glabellar sensation.
 - We have also used the ipsilateral infraorbital nerve to reconstruct corneal sensation.

Nerve harvest

- The tibial contribution to sural nerve is usually sufficient length. This can be harvested through a popliteal incision and a small counter incision in the midcalf.

Postoperative considerations

- Keep postoperative patients out of sports or vigorous activities for 6 weeks.
- Patients may experience pain once innervation occurs; this is actually a positive sign, but they should be warned in advance.

POSTOPERATIVE CARE

- Patients should be under the care of an ophthalmologist pre-, intra-, and postoperatively.
- The intraoperative tarsorrhaphy suture is left in place for 1 week.
- Patients are provided with postoperative topical medication:
 - Topical tobramycin and dexamethasone ointment until the tarsorrhaphy is removed
 - Topical moxifloxacin and prednisolone eyedrops
 - Preservative-free lubricating eyedrops
- Sensory and vision outcomes are monitored regularly by the ophthalmologist.

OUTCOMES

- To date, there have been only two series published describing outcomes in patients with corneal neurotization by Terzis²² and Borschel^{23,24} and a case report by Samii.
- In Terzis' series, all 6 patients were followed for an average of 16.3 ± 2.42 years and demonstrated significant improvements in corneal sensibility with no further deterioration of visual acuity or overall corneal health.²²

- In Borschel and Ali's series, using the described surgical technique for corneal neurotization, all patients demonstrated significant improvements in corneal sensation with some patients developing sensation indistinguishable from normal with Cochet-Bonnet esthesiometry; however, follow-up had not been carried out far enough to definitively determine vision outcomes.²³

COMPLICATIONS

- Axon regrowth through the nerve graft and into the cornea may take several months with this sural nerve grafting technique.
- Using the contralateral supratrochlear nerve results in minimal sensory loss on the donor side.
- Inability to regain protective sensation after corneal neurotization may be caused by unrecognized insufficiency of the donor nerve.
- Loss of sensation on the lateral ankle and foot after sural nerve harvest is of minimal functional consequence.

Section XIII: Brachial Plexus (Obstetrical Injury)

Primary Treatment of Neonatal Brachial Plexus Palsy

54
CHAPTER

Bryce R. Bell, Ji-Geng Yan, and Hani Matloub

DEFINITION

- Injury to the nerves supplying the upper extremity (C5-T1) during the birth process
- Epidemiology¹
 - Incidence can vary greatly by institution.
 - The most recent nationwide study shows 1.51 per 1000 live births in the USA.
- Risk factors¹⁻³
 - Shoulder dystocia
 - Macrosomia (greater than 4–4.5 kg)
 - Instrumented delivery
 - Prior delivery with brachial plexus injury
 - Prolonged labor resulting in hypotonia
 - Tachysystole during labor
 - Use of oxytocin
 - Studies have consistently shown that more than half of patients with neonatal brachial plexus palsy (NBPP) have no identifiable risk factor.

ANATOMY

- Normally, the brachial plexus has contributions from C5 to T1.
- Can have prefixed or postfixed cords with contributions from C4 (22%) and T2 (1%), respectively
- Roots combine to form upper (C5/C6), middle (C7), and lower trunks (C8/T1).
- Near the level of the clavicle, these trunks give off anterior and posterior divisions to form lateral, medial, and posterior cords, so named for their relation to the axillary artery. The lateral cord is formed from the confluence of the anterior divisions of the upper and middle trunks. The posterior cord is formed from the posterior divisions of all three trunks. Finally, the medial cord consists of only the anterior division of the lower trunk.
- Cords then divide into terminal branches (musculocutaneous, axillary, radial, median, and ulnar).
- Smaller branches originate from various levels in the brachial plexus and are important in localizing the level of injury by clinical examination (**FIG 1**).
- The sympathetic chain runs along the ventral aspect of the exiting roots and is often disrupted in root avulsions from the spinal cord. This accounts for the findings seen in Horner syndrome.

PATHOGENESIS

- Mechanism of injury
 - Most commonly a downward force on the shoulder causes deviation of the neck away from the involved extremity. This typically involves at least the C5-C6 roots but can result in complete plexus injury.
 - More rarely, injury can occur due to extreme cranial traction on the extremity with neck extension during breech delivery. These injuries often involve the lower roots.
 - Traditionally, injury was thought to be caused by traction during delivery by the obstetrician, by either manual or instrumented delivery.
 - However, given that more than half of children with brachial plexus injuries do not have an identifiable risk factor, some debate exists on the presence of an intrauterine mechanism of injury that is more difficult to identify. One study estimated uterine contractions exert up to 9 times greater force on the shoulder than that applied by the obstetrician.⁴
 - In addition, Walsh et al. showed no significant decrease in incidence of NBPP despite structured training on management of shoulder dystocia and a rising cesarean section rate.⁵
 - These injuries result in varying degrees of weakness in the ipsilateral

extremity, ranging from subtle weakness to flaccid paralysis.

- Classifications of Seddon and Sunderland

- Seddon divided nerve injuries into three categories: neurapraxia, axonotmesis, and neurotmesis.⁶

FIG 1 • The most common anatomy of the brachial plexus. The branching of the brachial plexus can be highly variable, and a thorough understanding of the most common variants is crucial prior to proceeding with brachial plexus exploration.

- Neurapraxic injuries have a transient loss of conduction, but do not undergo wallerian degeneration. In axonotmesis, the nerve is still externally in continuity but undergoes wallerian degeneration due to axonal disruption. Neurotmesis indicates a complete division of a nerve.
- Sunderland classified neurapraxia as type I and neurotmesis as type V. The axonotmesis category is divided into three separate categories, types II to IV, based on degree of internal injury short of complete division of the nerve.⁷ MacKinnon and Dellon later added a type VI injury, indicating multiple

degrees of injury in a single cross-sectional area of a nerve.⁸ This has been termed a neuroma-in-continuity.

- Wallerian degeneration occurs in axonotmetic and neurotmetic lesions due to axonal disruption. While there is some chance of recovery in axonotmetic lesions depending on the degree of internal injury, neurotmetic lesions will not recover without surgical repair or grafting.
- Contractures
 - Denervation leads to a progressive joint contracture due to muscle paralysis. This joint contracture was generally believed to be caused by muscle imbalance and fibrosis of denervated muscle groups. However, animal studies have shown that muscle contracture precedes fibrosis, indicating a separate, yet to be determined mechanism.⁹
 - Two types of joint contractures are seen in NBPP patients. The first is due to overpowering of affected muscles by their antagonists, as is seen with the internal rotation contracture at the shoulder in Erb palsy. The second is due to muscle contracture and shortening, as seen in the glenohumeral abduction contracture caused by the paralyzed deltoid or the elbow flexion contracture caused by the brachialis in Erb palsy.
 - Global shoulder dysfunction and glenohumeral deformity develop as early as 3 months due to unbalanced forces on the shoulder and may require open or arthroscopic reduction and tendon transfers for treatment.
 - It has also been shown that each segment of the upper extremity exhibits decreased length and girth compared to the unaffected extremity.¹⁰

NATURAL HISTORY

- In the past, full recovery had been reported to be as high as 95.7%.¹¹ However, more recent reports claim less optimistic spontaneous recovery rates in the 60% to 70% range.^{12,13}
- Upon closer analysis, it is clear that location and severity of injury, as well as the degree of spontaneous recovery by 3 to 6 months, can all dramatically change the prognosis for a given patient. Assessing these factors is essential to recommending a plan of care to the patient's parents.
- In patients with only mild weakness and rapid recovery within weeks, complete neurologic recovery is highly likely without surgical intervention.
- However, in patients with a flaccid upper extremity and Horner syndrome (indicating a complete brachial plexus injury with avulsion), acceptable recovery is extremely unlikely, and early surgical intervention at about 3

months is recommended. Even in the case where there is some degree of proximal muscle improvement, if the hand is still paralyzed at 3 months, one should proceed with surgical intervention to reinnervate the hand, as these patients are unlikely to recover meaningful hand function on their own.

- The remainder of neonatal brachial plexus patients fall between these two extremes, and the decision on the appropriate timing for intervention, if any, is still controversial.

PATIENT HISTORY AND PHYSICAL FINDINGS

- History should include a detailed maternal gestational history as well as patient birth history. The physician should seek specific information on the course of delivery, shoulder dystocia, instrumented delivery, respiratory distress or signs of hypoxia, and Apgar scores. This information can be helpful in ruling out other causes of apparent limb weakness or paralysis (ie, cerebral palsy, infection, fracture of the involved limb).
- Careful, systematic examination is crucial for making treatment decisions and comparisons over time. Given the importance of examination over time and the negative effects of delayed treatment, early referral to a multidisciplinary brachial plexus clinic is recommended. This will not only facilitate early surgical intervention when necessary but also ensure that patients receive prompt physical and occupational therapy to mitigate joint contracture formation while awaiting recovery.
- Physical examination should be performed with the child naked from the waist up to assess the entire upper extremity as well as the neck, chest, back, scapula, and abdomen. In the infant, physical examination relies heavily on observance of limb posture, spontaneous motion, neonatal reflexes, and passive motion.
- Certain postures have traditionally been associated with different levels of injury. The “waiter’s tip” posture describes a patient with the shoulder internally rotated, elbow extended, and wrist flexed. This posture would be suggestive of an upper plexus injury. Inversely, a patient with a lower plexus injury may have near normal shoulder and elbow function with a flaccid hand. A totally flaccid extremity indicates a complete brachial plexus injury.
- Horner syndrome describes a patient with ipsilateral ptosis, meiosis, and anhidrosis. This is indicative of a preganglionic avulsion from the spinal cord.
- There are many assessment tools and classification systems that can help synthesize information from the physical examination and assist in treatment decision-making. The most commonly used scores include the modified Mallet

scale, the Active Movement Scale, and the Toronto Test Score. All three of these scores have been assessed for inter- and intrarater reliability.

- The modified Mallet scale is a widely used measure of global shoulder function and does not grade specific muscles. It requires that the patient is mature enough to follow directions.
- The Active Movement Scale (AMS) is a detailed scoring of 15 different movements on a scale of 1 to 7. It was developed to quantify motor function in infants with NBPP and evaluate recovery over time. It can be used as early as 2 to 3 weeks of age by eliciting neonatal reflexes to assess specific joint movements.¹⁵
- The Toronto Test Score was developed to help predict recovery in children with NBPP. It can be used in young children who are unable to follow directions and tests five specific motions: elbow flexion, elbow extension, wrist extension, thumb extension, and finger extension.¹⁴

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Although the decision to proceed with primary nerve surgery for NBPP is a clinical one, further diagnostic testing can provide useful information in development of a surgical plan.
- Electrodiagnostic testing can be useful in determining preganglionic vs postganglionic lesions because avulsions will show normal sensory nerve action potential with no motor nerve conduction at the same level. However, these studies tend to overestimate the degree of recovery in NBPP and thus are not routinely used in surgical decision-making.
- Computed tomography (CT) myelography can also be useful in determining the presence of root avulsions preoperatively. One study showed 98% specificity, but only 37% sensitivity for CT myelography in diagnosing root avulsions if no rootlets are seen traversing the pseudomeningocele.¹⁶
- Another study compared CT myelography to MR myelography and found similar results for CT myelography to prior studies. However, MR myelography on a 3T magnet showed equivalent sensitivity and specificity without the need for lumbar puncture, intrathecal contrast injection, or ionizing radiation. Therefore, with improvements in technology, many now favor MR over CT myelography.¹⁷
- Other imaging modalities that some find useful are ultrasound to assess diaphragmatic motion and chest radiography to look for an elevated hemidiaphragm. Abnormal findings would indicate phrenic nerve injury. This

is particularly important if one is considering using the phrenic or intercostal nerves for plexus reconstruction.

DIFFERENTIAL DIAGNOSIS

- Spinal cord injury
- Pseudoparalysis
 - Septic joint
 - Upper extremity fracture
- Cerebral palsy

NONOPERATIVE MANAGEMENT

- Patients should be referred early to an occupational therapist with experience in neonatal brachial plexus injuries. Ideally, this therapist will see the patient at the same time as the surgeon to facilitate communication.
- Therapy should focus stretching and range of motion of the entire upper extremity to prevent contractures and maladaptive motions. It is particularly important to stabilize the scapula during shoulder range of motion and stretching to make sure motion is truly glenohumeral and not scapulothoracic.

SURGICAL MANAGEMENT

- The decision to proceed with microsurgical repair or reconstruction of the brachial plexus is perhaps the most controversial topic in management of neonatal brachial plexus injuries.
- As discussed earlier, most surgeons agree that infants with a flaccid extremity, Horner syndrome, or other signs of a preganglionic avulsion warrant early exploration and microsurgical intervention.
- Gilbert and Tassin popularized the absence of biceps function at 3 months as an indication to proceed with microsurgery.³ However, another study showed that when biceps function alone was used in decision-making, it would have incorrectly predicted recovery in 12.8% of cases.¹⁴
- The Hospital for Sick Children reports using AMS for initial evaluation of infants with NBPP. At 3 months, a conversion is made for scores of elbow flexion and elbow, wrist, thumb, and finger extension. The converted scores are then summed. If the score is above 3.5, then observation is continued and the patient re-evaluated every 3 months for continued improvement. If the patient fails to improve at each visit or fails the “cookie test” at 9 months, then microsurgery is scheduled.¹⁸

- After assessing the outcomes of patients managed by observation, microsurgery, and/or secondary orthopedic procedures (tendon transfer or external rotation osteotomy), Waters concluded that he would operate on infants with no return of biceps function by 5 months or a flail arm and Horner syndrome at 3 months.¹⁹
- We prefer to use the absence of any biceps function at 4 months as a trigger to proceed with surgery, re-evaluating monthly for continued improvement in those with some biceps function present at 4 months. Our center has performed surgery at up to a year for those that present late to our clinic for initial evaluation without biceps function. In these cases, we are likely to perform a bypass graft around the neuroma rather than neuroma resection and grafting, to avoid resecting any regenerated axons.

PREOPERATIVE PLANNING

- Once the clinical decision is made to proceed with surgery, develop a carefully considered operative plan that incorporates information from physical examination, imaging, and electrodiagnostic testing, if obtained.
- Review the results of the physical examination and imaging to estimate the number of roots involved and if they are ruptures or avulsions. The former are often amenable to neuroma resection and grafting, whereas the latter require neurotization from other levels or extraplexal nerves. If several levels are involved, prepare for transfer of nerves from outside the plexus to innervate critical targets for upper extremity function. This may require further workup with diaphragmatic ultrasound or chest radiographs to determine if the phrenic nerve or intercostal nerves are a suitable option for extraplexal neurotization.
- Consider what portion of the plexus is injured in a proximal to distal direction. Though most injuries are supraclavicular, more distal involvement may require a clavicular osteotomy and/or extension of the incision to expose the deltopectoral interval.
- In the case that the entire plexus is involved, the lower roots are usually avulsed, and options are limited for reinnervation. Although priority is usually given to elbow flexion and shoulder stability in adults, in NBPP, some advocate that priority should be given to grafting nerve roots supplying the hand because it is a shorter distance to regenerate than in adults, a greater capacity for healing, and more neural plasticity in the brain. In addition, there are proven extraplexal nerve transfer options for shoulder and elbow function.
- Failure to plan for all potential scenarios and their solutions not only prolongs

surgical time but may compromise the ultimate outcome for the patient if inappropriate decisions are made intraoperatively.

- The surgeon should request avoidance of muscle paralysis after induction of anesthesia to allow for assessment of signal transmission across neuromas via nerve stimulation.
- In some centers, pathology service is consulted to perform fresh frozen specimens for evaluation of neuromas to confirm resection to healthy axons before grafting.
- Neurology may be consulted for intraoperative evaluation of somatosensory evoked potentials (SSEPs). This can be extremely helpful when trying to distinguish between an intact root, an intraforaminal rupture, and an avulsion from the spinal cord. However, this requires special training on the part of the interpreting neurologist and is only available in a limited number of centers.

Positioning

- Some centers begin with the patient positioned in the prone position and perform bilateral sural nerve harvest prior to exploration. We prefer to begin in the supine position and perform the brachial plexus exploration prior to harvest, as this may avoid unnecessary nerve harvest if bilateral sural nerve grafts are not needed.
- For plexus exploration and reconstruction, the patient should be positioned supine with a small, transversely oriented roll placed at the level of the scapulae to extend the neck and to rotate to the contralateral side of the injury by improving access to the injured plexus.
- We also recommend placing the patient's head at the most proximal extent of the bed and the ipsilateral shoulder near the edge of the bed to improve positioning and access for the surgeon and assistants (**FIG 2**).
- It is crucial to assure that all bony prominences are well padded, as the procedure can last up to 12 hours. A Foley catheter with a temperature probe is also placed for urine output monitoring, fluid management, and avoidance of hypothermia.
- The patient should be prepped and draped from the level of the mandible proximally to just below the nipple on the ipsilateral chest and the ipsilateral extremity draped free (**FIG 3**).
- If considering use of the contralateral C7 nerve root, it will be necessary to prep and drape the contralateral chest and neck as well. In addition, both legs

should have a tourniquet placed on the thigh and be prepped and draped for a possible sural nerve harvest.

FIG 2 • The patient is positioned with the head at the most proximal extent of the bed and the ipsilateral shoulder near the edge of the bed to improve positioning and access for the surgeon and assistants. A transverse roll should be placed posteriorly at the level of the scapulae to allow neck extension and rotation away from the injured side.

Approach

- Although some surgeons use a straight incision paralleling the upper border of the clavicle for exposure, we prefer the use of an L-shaped incision.
- The proximal limb follows the posterior border of the sternocleidomastoid (SCM) muscle, and the transverse limb follows the superior border of the clavicle.
- We believe this improves access to the neural foramina to assess for proximal rupture vs avulsion from the spinal cord during initial exploration or end-to-side neurotization into the phrenic nerve, if necessary.

FIG 3 • The patient is prepped and draped from the level of the mandible proximally to just below the nipple on the ipsilateral chest, with the ipsilateral arm draped free. The incision is marked along the posterior border of the sternocleidomastoid (SCM) with the transverse limb following the superior border of the clavicle.

TECHNIQUES

■ Exposure

- The expected incision should be marked out clearly and hashed for correct closure at the conclusion of the case (see **FIG 3**). Formerly, our center injected the line of the incision with epinephrine diluted 1 to 400 000 to minimize blood loss during initial dissection. However, we have found that with careful dissection using electrocautery, epinephrine infusion is not necessary and eliminates a potential source of error in appropriate dilution.
- Dissection is taken down through the platysma with meticulous care to coagulate superficial vessels, attempting to minimize blood loss during the case. The flap is raised in the plane just below the platysma and reflected superolaterally to expose the posterior triangle. This is tied back with suture for retraction throughout the case.

- At this point, it may be necessary to reflect the clavicular head of the SCM and ligate the nearby external jugular vein to improve exposure of the anterior and middle scalene muscles and the more proximal nerve roots. The clavicular head of the SCM should be tagged and repaired at the conclusion of the case.
- Moving laterally, the omohyoid is either divided at its tendinous portion or tagged and retracted. The omohyoid is a consistent marker for the level of the suprascapular notch.
- During this exposure, the branches of the cervical plexus extending across the clavicle to the upper chest will be encountered and divided. With careful dissection, these can be traced proximally to identify the C4 root and then excised and used as additional nerve graft.
- There will be a fat pad at the level deep to the omohyoid that should be released from the clavicle, tagged, and reflected superolaterally. This should be repaired back to the clavicle during closure.
- Additionally, the transverse cervical vessels will cross the surgical field and may need to be ligated and cut to facilitate access to the supraclavicular brachial plexus.
- After this, the upper and middle trunks are often visible exiting between the anterior and middle scalene muscles. The junction of the C5 and C6 roots is the most common site for neuroma formation and is often visible now (**TECH FIG 1A**).
- Identify the phrenic nerve running in a cranial-to-caudal direction along the lateral border of the anterior scalene, and trace this proximally to its contribution from the C4 nerve root. Frequently the phrenic nerve gives off a contribution to the C5 nerve root. The identity of the phrenic nerve can be confirmed using a nerve stimulator and watching for contraction of the diaphragm. One should notify the anesthesia team to hold respiration during phrenic nerve stimulation to avoid confusion.
- This should give two markers confirming the levels of the brachial plexus. In many cases, the phrenic nerve is entrapped in scar tissue as it passes over the involved plexus, and care should be taken not to injure or excise it during dissection or neuroma resection.
- Often the anterior and middle scalene muscles are also included in the scar around the brachial plexus, and careful dissection is required to separate them and adequately expose the roots and the neural foramina (**TECH FIG 1B**).

- Once the levels have been appropriately identified, begin dissecting the C5 nerve root proximally to determine continuity all the way to the spinal cord. The branch to the long thoracic nerve should be identified during dissection of C5-C7 and protected initially. However, some or all of these branches may need to be sacrificed later during neuroma resection and grafting in the case of very proximal injuries.
- Carry out the same dissection proximally for C6-T1, inspecting closely for intraforaminal rupture or avulsion from the spinal cord. Again, the scalene muscles must be dissected free from the neuroma to allow enough retraction to inspect the more caudal C8 and T1 roots. In addition, caudal to C7, the subclavian vein and clavicle will need to be retracted to improve exposure. Take care to avoid violating the pleura just distal to T1.
- If there is uncertainty regarding whether or not a preganglionic avulsion exists, either a specimen can be sent for pathologic assessment to evaluate for involvement of the dorsal root ganglion or SSEPs can be evaluated if neurology service is available.

TECH FIG 1 • A. With the superficial dissection complete, the upper and middle trunks are often visible exiting between the anterior and middle scalene muscles. The junction of the C5 and C6 roots is the most common site for neuroma formation, and the neuroma is often visible now. **B.** In more severely scarred cases, accurate identification of individual roots and determining which levels are intact,

ruptured, or avulsed is often difficult. A nerve stimulator and intraoperative electrodiagnostic testing can be helpful.

- Next, dissect from proximal to distal along the cranial border of the C5 root and upper trunk to locate the suprascapular nerve exiting posteriorly toward the suprascapular notch. It is classically described as branching from the upper trunk. However, recent cadaver studies have shown that it often branches at or after the split of the anterior and posterior divisions of the upper trunk (most often from the posterior division) and can even have contributions from both the anterior and posterior divisions of the upper trunk.²⁰
- Continue laterally to identify the anterior division of the upper trunk and potentially the lateral pectoral nerve depending on its level of branching. This is traditionally described as branching from the lateral cord. However, it most often originates from the anterior division of the upper trunk rather than the lateral cord proper.²⁰
- Next dissect from the C7 root distally to identify the middle trunk with its anterior and posterior divisions. Continue this dissection distally until nerves are free of neuroma.
- Carry out the same dissection of the lower trunk distally to its anterior and posterior divisions and, if necessary, to the medial cord. Identify its branches as you dissect distally. It will be necessary to carefully dissect and retract the clavicle and subclavian vein during this portion of the dissection.
- Once all components of the plexus are identified, a nerve stimulator should be used to determine which portions of the brachial plexus are transmitting sufficient signals distally. Catalogue this information clearly and carefully to avoid neglecting essential functions during reconstruction.
- If infraclavicular access is also needed, this incision can be joined laterally with a standard deltopectoral incision near the coracoid process.
- Once the conjoined tendon is identified, the tendon can be tagged, cut, and reflected to expose the lateral, posterior, and medial cords as well as their terminal branches. This will be repaired at the conclusion of the case.

■ Neuroma Resection With Nerve Grafting

- Although neurolysis alone of a neuroma-in-continuity was performed in the past, it is no longer recommended due to inferior outcomes when compared to neuroma resection and grafting.²¹ Therefore, if it is determined that there is insufficient signal transmission across a neuroma, then resection and grafting should be performed.
- As mentioned in the prior section, careful dissection should be performed proximal and distal to the site of injury to ensure that there is a complete understanding of the injured structures. Do not presume a normal appearing nerve root proximal to a neuroma is not avulsed based solely on visual appearance. It is possible to have a two-level injury with avulsion from the spinal cord and a neuroma distally.
- Begin by sectioning the midportion of the neuroma and then at what appears to be normal nerve proximally and distally. Many centers will tag these specimens for orientation and send them for frozen section by the pathology department to determine whether the proximal and distal extent of the resection is free of fibrosis. Alternatively, perform an initial resection under loupe magnification, and then under the operating microscope, inspect the fascicular pattern to assess the adequacy of resection. Regardless, grafting to healthy stumps proximally and distally is important to assure fibrosis does not impair axon regeneration.
- Next, assess the length of nerve graft necessary to bridge each defect. This number will need to be multiplied by the number of cables necessary to match the size of the nerves being grafted. After a determination of the total length of graft needed, sural nerve harvest can be performed on one or both legs. This can be done open or endoscopically depending on surgeon preference and training. These techniques are described elsewhere in this text.
- If avulsions make grafting impossible at some levels, existing roots should be preferentially grafted to the medial and then posterior cords to restore hand function. Extraplexal nerve transfers can be used to reliably restore shoulder and elbow function in these cases, as will be described below.
- Coaptation of the nerves can be carried out using 9-0 or 10-0 nylon suture or fibrin glue depending on surgeon preference (**TECH FIG 2**).

TECH FIG 2 • After confirming intact roots and adequate neuroma resection, use the available graft material to reinnervate as many priority targets as possible.

■ Accessory (CN XI) to Suprascapular Nerve Transfer

- If you cannot graft directly to the suprascapular nerve from the upper trunk or the C5/C6 root, either because of avulsion of the upper roots or the need to divert those roots to other targets, external rotation of the shoulder can be restored through transfer of CN XI.
- Trace the transverse cervical artery posteriorly to where it enters the trapezius muscle. Localize the accessory nerve using a nerve stimulator.
- Next, trace the accessory nerve distally, past its innervation of the upper and middle portions of the trapezius. Mobilize and then cut the nerve, making sure there is sufficient length to reach the stump of the suprascapular nerve. The stump of the suprascapular nerve should be prepared such that it is as close as possible to its origin while still resecting to healthy axons.
- Transpose the accessory nerve over to the suprascapular nerve stump, and coapt the two using either nylon suture or fibrin glue, depending on surgeon preference (**TECH FIG 3**).

TECH FIG 3 • The spinal accessory nerve is followed caudally to the branch to lower trapezius, where it is transected and rotated laterally to innervate the suprascapular nerve.

■ Ulnar to Musculocutaneous Nerve Transfer

- If the lower trunk and medial cord are intact and the patient has demonstrated full ulnar nerve function preoperatively, a portion of the ulnar nerve can be used to reanimate the biceps muscle.
- Beginning at the inferior border of the pectoralis major tendon, make a longitudinal incision on the medial arm about 8 cm long. Dissect down to the biceps fascia, and separate it from coracobrachialis (**TECH FIG 4A**).
- Identify the motor branch to the biceps, which is about 13 cm distal to the acromion.²² Dissect this as far proximally into the musculocutaneous nerve as possible, and then transect it for transfer to the ulnar nerve.

TECH FIG 4 • A. The incision is marked beginning at the inferior border of the pectoralis major tendon and extended distally along the medial border of the biceps tendon. **B.** After isolating the fascicles of the ulnar nerve to FCU as distally as possible, transect the motor branch to biceps as proximally as possible to assure there is no tension on the repair.

- Dissect posteriorly to locate the median and then ulnar nerves. If there is any confusion, a nerve stimulator can be used to differentiate the two.
- Using the microscope, make an epineurotomy in the ulnar nerve, and harvest two fascicles from the ulnar nerve. Use the nerve stimulator to confirm that they contain motor fibers, and section them distally enough that they can be transposed anteriorly to meet the biceps motor branch without tension.
- Coapt the ulnar nerve fascicles to the biceps motor branch under the microscope using either nylon suture or fibrin glue (**TECH FIG 4B**). Some surgeons will perform a similar transfer of median fascicles to the FCR flexor carpi radialis (FCR) to the motor branch to the brachialis in conjunction with this procedure for added elbow flexion strength.

■ Intercostal to Musculocutaneous Nerve Transfer

- If the ulnar nerve is not an option for restoration of elbow flexion, two to three intercostal nerves can be transferred in a similar manner.
- If you have already made the incision in the deltopectoral groove to expose the infraclavicular plexus, then you can extend this inferomedially across the chest. If not, then make an anterior axillary incision and extend your incision

inferomedially, perpendicular to the ribs down to the level just inferior to the nipple. Retract the pectoralis major tendon superiorly to expose the musculocutaneous nerve at its take off from the lateral cord. It should be sectioned here and mobilized for later coaptation with the cables from the intercostal nerves (**TECH FIG 5A**).

- Limit resection of the fat and the associated lymph nodes in the axillary fossa. However, dissect sufficiently to expose the involved structures and a more direct line for coaptation of the intercostal and musculocutaneous nerves.
- Dissect down to the ribs. It may be necessary to release portions of the origin of the pectoralis major and serratus anterior muscles. These should be tagged for repair at the conclusion of the case.
- Expose the second, third, and fourth ribs subperiosteally. The intercostal nerves from roots T2 to T4 are inferior to their respective ribs after dissecting through the external and internal intercostal muscles.
- Carefully dissect the intercostal nerves anteriorly to the mammary line and posteriorly to the point where they will be transposed toward the musculocutaneous nerve.
- Cut the intercostal nerves about 1 cm medial to the mammary line, and carefully mobilize each nerve posteriorly such that there is sufficient length to reach the musculocutaneous nerve in the axilla.
- Coapt the intercostal nerves as a cable graft to the musculocutaneous nerve as far distal as possible without tension or kinking, to minimize the distance for regeneration. Coaptation can be performed with nylon suture or fibrin glue, per surgeon preference (**TECH FIG 5B**).
- Make sure that there is no tension on the nerve coaptation site with the arm in 90 degrees of abduction and 90 degrees of external rotation.

TECH FIG 5 • A. Mark out an anterior axillary incision, and extend your incision inferomedially, perpendicular to the ribs down to the level just inferior to the nipple. **B.** Cut the intercostal nerves about 1 cm medial to the mammary line, and carefully mobilize each nerve posteriorly such that there is sufficient length to reach the musculocutaneous nerve in the axilla. These will be transferred to the musculocutaneous nerve as a cable.

■ Radial to Axillary Nerve Transfer

- For this procedure, we prefer the patient to be flipped prone with the involved extremity prepped into the field and forearm either at the side or resting on the lower back. As mentioned before, paralysis should be avoided after induction of anesthesia to allow for use of the nerve stimulator.
- Make a J-shaped incision from the lateral border of the scapula, following the posterior border of the deltoid and extending down the posterior aspect of the upper arm (**TECH FIG 6A**).
- Dissect down to the fascia overlying the triceps and deltoid, watching for the lateral cutaneous branch of the axillary nerve. This can be used to trace proximally to the axillary nerve as it passes through the quadrangular space.

- Transect the axillary nerve just proximal to the teres minor motor branch, and transpose the nerve distally.
- Find the radial nerve as it passes through the triangular space, and trace it as distally to locate the motor branch the medial head of the triceps muscle. Transect the nerve as distally as possible such that there is sufficient length for tension-free repair.
- Transpose the triceps nerve branch proximally. Remove the lateral cutaneous nerve from the axillary nerve.
- Under the microscope, coapt the triceps motor branch to the axillary stump using nylon suture or fibrin glue. 8-0 or 9-0 suture is appropriate. Intercalary grafts are usually not needed (**TECH FIG 6B**).
- Abduct and rotate the arm to make sure that there is no tension on the repair with shoulder motion.

TECH FIG 6 • A. A J-shaped incision is marked from the lateral border of the scapula, following the posterior border of the deltoid and extending down the posterior aspect of the upper arm allowing exposure of the axillary nerve in the quadrangular space and the radial branch to the medial head of the triceps distally. **B,C.** The branch to the medial head of the triceps is transected as distally as possible and transposed proximally to meet the motor branch of the deltoid. A branch to the lateral or long head of the triceps could also be used if better for coaptation. No branch has been shown to be functionally superior to the others.

PEARLS AND PITFALLS

Preoperative planning

- Develop a complete understanding of the injury prior to surgery, as well as a plan with multiple alternatives. This facilitates efficiency during a long procedure and minimizes the chance of overlooking important targets for reinnervation.

Exploration

- It is crucial to fully explore each involved nerve root to its insertion in the spinal cord, even if it is involved in neuroma distally. Grafting from an avulsed nerve root assures complete failure of the surgery at that level.

Neuroma resection

- Use available resources to confirm adequate neuroma resection as grafting to a fibrotic nerve ending will limit or completely block nerve regeneration.

Reconstruction

- When there are limited intact nerve roots for grafting, preferentially graft to the lower trunk and medial cord as there are no proven extraplexal transfers for animating the hand but multiple options for extraplexal transfers for the shoulder and elbow.

Therapy

- Appropriate therapy before and after surgery is at least as important as a technically excellent repair or reconstruction. Maintaining full passive motion of all involved joints gives the recovering neuromuscular units the best chance to succeed. A strong relationship with a trusted occupational therapist, experienced in brachial plexus injury, is crucial for success.

POSTOPERATIVE CARE

■ Acute phase (0–4 weeks)

- Place the patient in cervical collar and shoulder immobilization dressing for 3 weeks in order to protect repairs. We perform weekly dressing changes in our therapy clinic to monitor the incisions as well as for skin breakdown in the axilla and between the forearm and abdomen.
- After 3 weeks of immobilization, begin gentle active and passive range-of-motion exercises for the neck, scapula, shoulder, elbow, and hand. We recommend two formal therapy visits per week initially.

■ Subacute phase (4 weeks to 2 years)

- Monitor active and passive range of motion and return of muscle function.
- Review and adjust home therapy program to emphasize the importance of consistency in performing exercises at home and to address any developing contractures early.

OUTCOMES

- Outcomes in brachial plexus surgery can be highly variable depending on the number of levels involved, the number of avulsion injuries, and the willingness or ability of the patient's family to participate in therapy.
- In patients undergoing nerve transfer or grafting, it may take 6 to 9 months to see any function in the involved muscle groups. Continued improvement can be seen for 2 to 4 years as patients continue to make gains in strength and coordination.
- It should be emphasized repeatedly to parents that therapy must continue at home until the child reaches skeletal maturity. Excellent early outcomes can be lost if therapy is neglected for any period of time, especially during a growth spurt.

COMPLICATIONS

- Injury to major vessels of the neck and upper extremity
- Failure to recover function after plexus reconstruction
- Pneumothorax
- Seroma formation
 - After axillary dissection during nerve transfers
 - With thoracic duct injury when exploring the left brachial plexus

55 Secondary Neonatal Brachial Plexus Palsy Reconstruction

CHAPTER

Joshua M. Adkinson

DEFINITION

- Neonatal brachial plexus palsy (NBPP) results from injury to any brachial plexus nerve root (C₅-T₁) during a difficult delivery.^{1,2}
- Persistent paralysis and progressive spasticity, contractures, joint instability, and bony deformities of the upper extremity may occur in children with incomplete recovery of nerve function.
- The type, severity, and manifestations of NBPP vary greatly between patients and surgical options for treatment must be individualized.

ANATOMY

- Most commonly, the C₅C₆ roots are involved (Erb palsy), leading to deficits of shoulder abduction and external rotation (supraspinatus, infraspinatus, and deltoid), elbow flexion (biceps brachii, brachialis), and forearm supination (supinator).
- C₇ involvement causes paralysis of the subscapularis, teres major (TM), clavicular head of the pectoralis major (PM), brachioradialis (BR), extensor carpi radialis longus (ECRL) and brevis (ECRB), and possibly extensor carpi ulnaris and extensor digitorum communis (EDC). This leads to the classic “waiter tip” posture,³ with deficits of wrist and finger extension.
- Rarely, the C₈T₁ roots alone are affected (Klumpke palsy), leading to weakness/paralysis in the wrist/finger flexors and hand intrinsic muscles.
- Complete plexus involvement (C₅-T₁) leads to a flail extremity.

PATHOGENESIS

- Between 50% and 92% of patients with NBPP experience complete recovery of function without primary nerve reconstruction.^{1,4–8} In those with persistent deficits, the clinical findings will vary over time.
- Secondary deformities are impacted by the severity of the initial nerve injury, extent of muscle recovery, patient age at presentation, and previous treatments.
- In addition to paresis/paralysis of affected muscles, co-contraction of antagonistic muscles can occur in patients with partial recovery.⁹ This may lead to contracture and/or joint deformity.
- The most common posture in children with NBPP is internal rotation of the shoulder, flexion of the elbow, supination of the forearm, and ulnar deviation of the wrist, with variable involvement of the fingers.¹⁰ Many children also develop a limb-length discrepancy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The preoperative evaluation of children with secondary NBPP deformities includes a detailed history, an assessment of functional limitations, and measurements of active and passive range of motion.
- Grading function
 - No grading systems are universally recommended for assessment of elbow, forearm, wrist, and hand function in patients with NBPP.
- Physical Examination
 - Function is observed, active and passive ranges of motion are documented, and muscle strength is assessed with and without gravity.
- Elbow
 - Co-contraction of the elbow flexors and extensors are assessed. Dislocation of the radial head and proximal ulna are noted.
- Forearm
 - Long-standing supination or pronation deformities may lead to fixed contracture of the interosseous membrane (IOM). Continued growth can then lead to bowing of the radius and ulna, dorsal dislocation of the distal ulna, and/or posterior dislocation of the radial head.
- Wrist
 - Ulnar deviation is common because of paralysis of the ECRL and ECRB.
- Hand
 - Limited metacarpophalangeal (MCP) joint extension is common, as is thumb instability.¹¹

IMAGING

- Anteroposterior and lateral radiographs of the elbow or wrist may be obtained to evaluate for joint subluxation/dislocation or articular deformities (**FIG 1**).

NONOPERATIVE MANAGEMENT

- All patients should undergo physical therapy, with the goal of muscle strengthening and full passive range of motion of the elbow, forearm, wrist, and fingers.
- Orthoses are used to maintain anatomic joint alignment and to prevent contracture.
- Botox injection into spastic musculature is effective for temporary (3–6 months) muscle weakening.

SURGICAL MANAGEMENT

- Surgical options include tendon transfers, arthrodeses, osteotomies, muscle/tendon releases, and functioning muscle transfers.
- Secondary reconstruction of the elbow, forearm, wrist, and hand is considered in children older than 4 years with incomplete recovery of upper extremity function after primary reconstruction or in those who present after the optimal window for nerve reconstruction.^{10,12–15}

FIG 1 • Right radial head dislocation (*arrow*) in long-

standing brachial plexus palsy.

- Restoration of elbow flexion is the priority, followed by wrist extension, thumb/finger flexion, wrist flexion, thumb/finger extension, and intrinsic hand reconstruction.
- Elbow flexion contractures greater than 40 degrees are an indication for surgical release. Less significant contractures can be released, but this may cause clinically significant elbow flexion weakness.
- Weak elbow flexion (less than MRC grade 3) may be addressed via Steindler flexorplasty or transfer of the latissimus dorsi (LD), PM, or triceps.
- The surgical approach to the forearm depends upon the underlying deformity. Supination contractures are best treated by a biceps rerouting. If there is minimal passive range of motion, IOM release or pronation osteotomy of the radius is recommended.
- Pronation deformities are treated by pronator teres (PT) release or rerouting. One must ensure good passive supination prior to PT rerouting.
- Weak wrist extension can be managed by transfer of the flexor carpi ulnaris (FCU) to the ECRB or ECRL (to counterbalance an ulnar deviation force). Weak finger extension can be managed with a combination of palmaris longus/flexor digitorum superficialis (FDS)_{middle} or FDS_{middle}FDS_{ring} transfer to the extensor pollicis longus (EPL) and EDC tendons, respectively.
- In patients with a total (pan-plexus) palsy, free functioning muscle transfers (eg, contralateral LD, gracilis, rectus femoris) are the procedure of choice.

Preoperative Planning

- Radiographs of the affected extremity should be reviewed, if relevant.

Positioning

- The patient is positioned supine on the operating room table with the affected extremity on a hand table. A well-padded tourniquet is placed high on the arm for procedures distal to and including the elbow.
- For pedicled LD muscle transfer, the patient is placed in the lateral decubitus position.
- The gracilis muscle harvest requires a frog leg position.

Approach

- Elbow approach: The muscles causing an elbow flexion contracture (brachialis, biceps brachii, and BR) are approached via an antecubital incision.
 - Procedures to restore elbow flexion require a technique-specific approach.
- Forearm approach: The biceps tendon is approached through an antecubital fossa incision. The entire length of the tendon and portion of the radius under which the tendon is rerouted must be visualized.
- Wrist/fingers approach: Procedures to restore wrist and finger function require a technique-specific approach. The FCU tendon may be approached through a single longitudinal incision or several stepcut incisions.
 - Free functioning muscle transfers to restore finger flexion require an extensile approach from the anterior upper arm across the acromion and lateral clavicle. This provides full visualization of the proposed site of origin of the transferred muscle as well the adjacent neurovascular structures to be protected and/or used for vascular anastomoses and nerve coaptation.

ELBOW RECONSTRUCTION

TECHNIQUES

■ Elbow Release

- Landmarks: median nerve, radial nerve, lateral antebrachial cutaneous nerve (LABC), brachial artery, brachialis muscle, biceps brachii muscle, BR (**TECH FIG 1**)
- Depending on the severity of the contracture, a curvilinear or Z-plasty incision is made and the lacertus fibrosus is identified and divided (**TECH FIG 2A,B**).
- The median nerve/brachial artery is identified and retracted medially and the LABC is retracted laterally.
- If fractional lengthening is indicated, then two incisions 1 cm apart are made with electrocautery at the musculotendinous junction of the brachialis. The anterior half of the BR is elevated from the humerus while protecting the radial nerve. The medial half of the biceps tendon is incised distally and the

lateral half proximally to provide lengthening. The release is reinforced with 3-0 braided suture, as needed.

- If a full release is indicated, then the biceps tendon is Z-lengthened¹⁶ (**TECH FIG 2C**), the brachialis is divided, and the BR is completely elevated from the humerus while protecting the radial nerve. The anterior elbow capsule is incised, if necessary. In long-standing contractures, foreshortened neurovascular structures will limit full passive elbow extension.
- The biceps tendon is reapproximated using 3-0 braided suture with the elbow in 30 degrees of flexion (**TECH FIG 2D**).
- The skin is closed in layers (**TECH FIG 2E**).

TECH FIG 1 • Structures crossing the elbow.

TECH FIG 2 • Approaches to elbow release. **A.** Curvilinear approach to the elbow. **B.** Z-plasty approach to the elbow. **C.** Steps in a biceps Z-

lengthening. **D.** Z-lengthened biceps tendon prior to reapproximation. **E.** Wound closure with a Z-plasty at the elbow (*arrow*).

■ Restoration of Elbow Flexion

Steindler Flexorplasty (**TECH FIG 3**)

- Landmarks: medial epicondyle, median nerve, ulnar nerve, brachial artery, humerus, biceps brachii muscle, brachialis muscle
- Fifteen-centimeter medial elbow curvilinear incision is made, and the skin flaps are elevated above the fascia while protecting the medial antebrachial cutaneous nerve.
- The ulnar nerve is retracted medially and the median nerve and brachial artery are retracted laterally.
- The flexor-pronator mass is freed from osseous attachments distally. Using an osteotome, the flexor-pronator origin at the medial epicondyle is elevated with a 2-cm segment of bone.
- The humerus is exposed deep to the brachialis. Approximately 5 to 7 cm proximal to the elbow joint, a bur is used to create a cortical window in the humerus.¹⁷
- With the elbow in 130 degrees of flexion, the medial epicondyle/flexor-pronator mass is secured to the humeral corticotomy using a 3.5-mm compression screw over a washer.

TECH FIG 3 • Steps in a Steindler flexorplasty.

- The ulnar nerve is transposed anteriorly to prevent tethering and the muscle is closed over the exposed osteotomy site using absorbable suture.
- The skin is closed in layers.

Latissimus dorsi Transfer (Pedicled) (**TECH FIG 4**)

- Landmarks: thoracodorsal neurovascular bundle, rhomboid muscle, teres major and minor muscles, acromion, clavicle, biceps brachii tendon
- Bipolar (moving the muscular origin and insertion) transfer is preferred because it increases the mechanical efficiency of the transfer and decreases the chance of vessel twisting/kinking.¹⁸
- Harvest—5-cm wide elliptically oriented skin paddle (8 cm distal to the axilla) is designed over the midaxis of the muscle and incised with superolateral and inferomedial extensions.

- The skin flaps are elevated off of the muscle and the arm is fully abducted and flexed.
- The muscle is marked at resting tension using 3-0 silk sutures placed at 5-cm intervals.
- The origin of the muscle is released and the muscle is elevated toward the axilla.
- The thoracodorsal neurovascular pedicle is identified on the deep surface of the muscle and dissected to its origin from the axillary artery. All adventitia is freed from the vessel to prevent tethering during transfer.
- The LD insertion is released from the bicipital groove of the humerus using electrocautery.
- Inset—a curvilinear longitudinal incision is made over the anterior upper arm with a transverse extension over the acromion and lateral clavicle.
- The skin flaps are elevated, and a deltopectoral window is created through which the muscle flap is passed, origin first. Confirmation of the neurovascular pedicle orientation is mandatory at this juncture.
- The insertion of the muscle is secured to the acromion and clavicle using two previously placed suture anchors.
- With the elbow in 100 degrees of flexion and full supination, the distal muscle is tubularized and secured to the distal biceps tendon with 2-0 braided suture or with suture anchors to the radial tuberosity.

TECH FIG 4 • Steps in a latissimus dorsi transfer for elbow flexion.

- Two drains are placed in the donor site and all wounds are closed in layers.
- The skin paddle is used for postoperative muscle flap perfusion monitoring.

Free Functioning Gracilis Transfer

- Landmarks: thoracoacromial artery, acromion, clavicle, biceps brachii tendon, PM, intercostal muscles, adductor magnus, adductor longus
- Harvest—a longitudinal incision is made 2 cm posterior to the palpable adductor longus tendon on the medial upper thigh. The gracilis muscle is

identified and freed from surrounding soft tissues.

- The obturator nerve is identified and dissected proximally toward the adductor hiatus where it is divided sharply.
- The medial circumflex femoral artery and vein are dissected to their origin on the deep femoral vessels between the adductor longus and magnus. Branches to the adductor longus must be carefully ligated and divided (**TECH FIG 5A**).
- The muscle is marked at resting tension using 3-0 silk sutures placed at 5-cm intervals.
- A 4-cm longitudinal incision is made overlying the medial proximal tibia. The sartorius fascia is divided and the distal gracilis tendon (the most superior structure of the pes anserinus) is identified and sharply release from the tibia.
- Inset—a curvilinear longitudinal incision is made over the anterior upper arm with a transverse extension 2 cm above the acromion and lateral clavicle. The distal biceps tendon is exposed while protecting the neurovascular structures.
- The thoracoacromial artery (or brachial artery) and cephalic vein are prepared and the spinal accessory nerve is dissected free from the deep surface of the anterior trapezius muscle, ensuring maximum length for transfer (**TECH FIG 5B,C**). The intercostal nerves are an alternative donor for motor reinnervation.¹⁹
- The medial circumflex vessels are ligated and the muscle is transferred to the arm.
- The muscle position is evaluated relative to the anticipated neurovascular repairs and the muscle is secured to the acromion and clavicle using two previously placed suture anchors.
- The vessel anastomoses and nerve coaptations are performed with 9-0 and 10-0 nylon suture, respectively.
- With the muscle at resting tension and the elbow flexed to 100 degrees, the gracilis tendon is woven into the distal biceps tendon with 2-0 braided suture or secured to the radial tuberosity with suture anchors.
- The wounds are closed in layers (**TECH FIG 5D**).
- An implantable venous Doppler is used to monitor perfusion in combination with clinical examination.
- The patient is placed on 81 mg of aspirin daily for 4 weeks.

TECH FIG 5 • **A.** Free functioning gracilis muscle transfer harvest. **B.** Free functioning gracilis transfer with spinal accessory motor nerve. **C.** Free functioning gracilis transfer with intercostal motor nerves. **D.** Free functioning gracilis muscle transfer inset and closure.

FOREARM RECONSTRUCTION

■ Biceps Rerouting

- Landmarks: biceps muscle, brachialis muscle, BR muscle, lacertus fibrosus, brachial artery and branches, recurrent radial artery, median nerve, radial nerve, LABC
- A curvilinear incision is made over the antecubital fossa and the LABC is identified and protected.
- The radial nerve is identified between the brachialis and BR and protected. The brachial artery and median nerve are also identified and gently retracted for protection. The radial recurrent artery is ligated, if necessary.
- The lacertus fibrosus is divided and the biceps tendon is traced to the interval

between the BR and PT such that the biceps insertion into the radius is visualized.

- The biceps tendon is then divided with a Z-lengthening technique.²⁰
- The distal biceps tendon is rerouted dorsolaterally around the radial neck using a curved clamp. The rerouted tendon is then secured to the proximal biceps tendon in a side-to-side fashion using 3-0 braided with the elbow in 90 degrees of flexion and the forearm in full pronation (**TECH FIG 6**).

TECH FIG 6 • Biceps tendon rerouting.

■ PT Release/Rerouting

Video p8-c053_02

- Landmarks: BR, ECRL, ECRB, radius, radial artery, superficial radial nerve
- Six-centimeter skin incision at the volar radial aspect of the midforearm (**TECH FIG 7A**).
- The forearm fascia is divided and the BR and ECRL are retracted dorsally (**TECH FIG 7B**).
 - The superficial radial nerve lies under the BR and should be protected.
- The PT is detached from the insertion on the radius (the release is complete at this step). If rerouting is planned, then a 3-cm sleeve of the periosteum is taken with the PT to ensure adequate length for rerouting (**TECH FIG 7C**).
- The PT is mobilized proximally to allow for easy excursion.
- The IOM is released at the site of reinsertion and the PT is passed from volar to dorsal through a window in the IOM.
- The forearm is supinated and the PT is reinserted into the radius. In children, a 3-0 braided is woven into the PT tendon and passed through two transosseous drill holes to secure the PT to the radius (**TECH FIG 7D**). This is facilitated with the use of a Hewson suture passer.
 - In adults, a suture anchor may be used to secure the PT to the radius.
- The tourniquet is deflated, hemostasis is ensured, and the incision is closed in layers.

TECH FIG 7 • **A.** Approach for pronator teres exposure. **B.** Exposure of pronator teres insertion on the radius. **C.** Pronator teres elevation with a strip of the periosteum. **D.** Transosseous suture placement and docking of pronator teres onto dorsal radial shaft.

WRIST/FINGERS RECONSTRUCTION

■ FCU to ECRB Tendon Transfer for Wrist Extension

Video p8-c053_01

- Landmarks: FCU tendon, ulnar artery, ulnar nerve, ECRB tendon, ECRL tendon, EDC tendons
- A 10-cm incision made over the palpable FCU tendon extending proximally from the pisiform (**TECH FIG 8A**).
- The FCU is released from the pisiform, and the muscle/tendon unit is elevated while protecting the ulnar artery and nerve (**TECH FIG 8B**).
- A 6-cm incision is made over the distal dorsal forearm in line with the middle finger ray. The second extensor compartment is opened sharply, and the ECRB tendon is identified.

TECH FIG 8 • **A.** Markings for FCU to ECRB transfer, pronator rerouting, and thumb adductor release. **B.** FCU muscle/tendon exposure. Ulnar neurovascular bundle sits just deep to the tendon. **C.** The FCU to ECRB transfer was performed in combination with EPL rerouting. **D.** Preoperative right wrist extension. **E.** Postoperative right wrist extension.

- A wide subcutaneous tunnel is created to directly connect the FCU muscle to the proposed intersection with the ECRB tendon.¹¹ In the setting of ulnar wrist deviation, the FCU is instead woven into the ECRL to achieve radial balance.
- With the wrist in 30 degrees of extension, the FCU tendon is interwoven into the ECRB tendon using an end-to-side Pulvertaft weave with 3-0 braided suture (**TECH FIG 8C**).
- Hemostasis is ensured, and the incisions are closed in layers.
- The preoperative and postoperative posture of the right wrist is shown in **TECH FIG 8D,E**.

■ Free Functioning Gracilis Transfer for Finger

Flexion

- Landmarks: thoracoacromial artery, acromion, clavicle, intercostal muscles, adductor magnus, adductor longus, FPL, and FDP tendons
- See Restoration of Elbow Flexion technique, earlier, for harvest and proximal inset details. The muscle may also be directly attached to the humerus via suture anchors if additional distal length is necessary.
- A pulley is created at the elbow using either the PT or the FCU to optimize gracilis muscle excursion.²¹
- With the muscle tension set at resting length, the elbow at 90 degrees of flexion, and the MCP joints at 45 degrees of flexion, the gracilis tendon is woven obliquely through the FDP and FPL tendons in the distal third of the forearm and secured using 3-0 Ethibond suture. The FPL tendon junction with the FDP tendons is performed to ensure that the thumb does not flex prior to the digits (**TECH FIG 9**).
- Hemostasis is ensured and the incisions are closed in layers.
- An implantable venous Doppler is used to monitor perfusion in combination with clinical examination.
- The patient is placed on 81 mg of aspirin daily for 4 weeks.

TECH FIG 9 • Free functioning gracilis muscle for finger flexion.

PEARLS AND PITFALLS

ELBOW RECONSTRUCTION

Elbow release

- Electrocautery should be used to decrease bleeding during myotomy.
- Identify and protect the radial nerve during BR elevation.
- In long-standing contractures, the neurovascular structures will shorten and prevent full passive extension.
- Z-lengthening of the biceps tendon should be performed over as long a stretch of the tendon substance as possible.
- Extreme care should be taken when handling the thin biceps tendon during repair.
- Patients with weak flexion may have a functional loss of elbow flexion power after full release.

Steindler flexorplasty

- Small nerve branches to the flexor-pronator muscles and the medial collateral ligament of the elbow must be protected.
- Ensure good wrist extension power to counteract the possible development of a wrist flexion contracture. If active wrist extension is poor, simultaneous wrist arthrodesis can be performed.
- Concomitant ulnar nerve transposition is recommended to prevent traction on the nerve after muscle transposition.
- Ensure that the median nerve and brachial artery are free from compression or traction prior to securely fixing the transposed medial epicondyle/flexor-pronator mass.

LD transfer

- High brachial plexus lesions may preclude use of this transfer.
- Inclusion of a skin island will simplify recipient site closure.
- The muscle can be debulked to accommodate the upper arm soft tissue pocket.
- The neurovascular structures should be assessed repeatedly during transfer in an effort to avoid kinking/twisting.

Free functioning gracilis transfer

- Avoid nerve grafts, if at all possible.
- If normal (unaffected by the NBPP), the LD transfer results in better elbow flexion strength than the free gracilis transfer.
- Delay revision surgery for at least 1 year or after skeletal maturity.

FOREARM RECONSTRUCTION

Biceps rerouting

- Overtensioning of the transfer may lead to an elbow flexion contracture.
- The tendon may be fragile, and care should be taken to prevent fraying during handling.
- It is essential to Z-lengthen the entirety of the tendon to ensure

	adequate length for rerouting. ■ The posterior interosseous nerve is at risk during rerouting because it lies directly on the radius. ■ A concomitant IOM release is recommended if there is no passive pronation. ■ A BR rerouting in the forearm is recommended in patients without adequate triceps function, because biceps rerouting will impart an unopposed flexion force across the elbow.
PT release/rerouting	■ The superficial radial nerve and radial artery must be protected throughout the procedure. ■ The periosteal sleeve must be carefully elevated from the radius to provide adequate length for rerouting and reinsertion into the radius.
WRIST/FINGERS RECONSTRUCTION	
FCU to ECRB tendon transfer	■ If passive flexion of the wrist to 20 degrees is not possible, the tension is too great and the muscle weave must be loosened. ■ Avoid lifting the tendons from the wound when performing the weave because this will result in a lax repair. ■ Ensure that the subcutaneous tunnel through which the tendon is passed is wide and straight. ■ Wrist arthrodesis is a better option in children with weak wrist flexors.
Free functioning gracilis transfer	■ Delay revision or adjunctive procedures for at least 1 year or after skeletal maturity. ■ In children with weak or absent wrist extension, wrist arthrodesis may be considered in the future to direct the full force of flexion to the finger flexors.

POSTOPERATIVE CARE

Elbow Reconstruction

- Elbow release
 - No immobilization is necessary after a fractional lengthening of the elbow flexors. Immediate active and passive range of motion is initiated.
 - A full elbow release requires a long-arm orthosis for 4 weeks with initiation of active and passive range of motion. A nighttime extension orthosis is worn for 3 months.
- Steindler flexorplasty

- The elbow is immobilized in a long-arm orthosis for 6 weeks.
- After 6 weeks, gentle elbow extension and flexion are initiated under guidance of a hand therapist.
- Resistance exercises are introduced at 12 weeks.
- LD transfer
 - The elbow is immobilized at 100 degrees of flexion in a sling for 6 to 8 weeks. At 4 weeks, the patient is instructed to begin muscle contraction exercises.
 - At 8 to 10 weeks, active elbow extension and flexion are initiated under guidance of a hand therapist; re-education of the transferred muscle is often necessary.
 - Resistance exercises are introduced at 12 weeks.
- Free functioning gracilis transfer
 - The elbow is immobilized for 6 weeks in a position of 100 degrees of elbow flexion and the forearm in neutral.
 - Passive range of motion is initiated at 6 weeks, but passive flexion is restricted beyond 30 degrees for 12 weeks.
 - Re-education of the transferred muscle is necessary and EMG biofeedback is helpful.²²
- Contraction of the transferred muscle typically begins around 4-6 months postoperatively.

Forearm Reconstruction

- Biceps rerouting
 - The arm is immobilized in a long-arm cast with the elbow in 30 degrees of flexion and maximal pronation.
 - At 4 weeks, passive range-of-motion exercises are initiated and the patient is transitioned to a long-arm orthosis.
 - At 6 weeks, active elbow extension and flexion are initiated under guidance of a hand therapist.
 - The orthosis is discontinued at 8 weeks and resistance exercises are introduced at 10 weeks.
- PT release/rerouting
 - The forearm is placed in full supination using an above elbow orthosis for 6 weeks.
 - The patient is then allowed unrestricted motion under the supervision of a

hand therapist.

Wrist/Fingers Reconstruction

- FCU to ECRB tendon transfer
 - The wrist is immobilized in 30 degrees of extension for 4 weeks.
 - After 4 weeks, gentle range-of-motion exercises are begun and an orthosis is worn for an additional 4 weeks.
- Free functioning gracilis transfer
 - The arm is immobilized for 4 weeks with the elbow at 90 degrees of flexion, the wrist in neutral, and the fingers in at least 45 degrees of flexion at the MCP joints and interphalangeal joints.
 - At 4 weeks, a custom orthosis is created and a passive stretching program is initiated under the guidance of a hand therapist.
 - Upon spontaneous muscle contraction, the patient is directed to attempt active flexion of the fingers.
 - Therapy should continue for up to 1 year.
 - Re-education of the transferred muscle is necessary and EMG biofeedback is helpful.²²
 - Contraction of the transferred muscle typically begins around 4-6 months postoperatively.

OUTCOMES

Elbow Reconstruction

- Elbow release: fractional lengthening will increase elbow extension by 40 to 60 degrees, with minimal loss of elbow flexion power.²³⁻²⁵
 - A full elbow release will increase elbow extension by 50 degrees but leads to a 19-degree loss of active flexion.²⁵ Many patients are able to accomplish tasks that were difficult before surgery.
- Steindler flexorplasty: Al-Qattan²⁶ reports that patients can expect 110 degrees of active elbow flexion against resistance, with a mean postoperative elbow flexion contracture of 35 degrees.
- LD transfer: Most patients will achieve M4 elbow flexion strength after transfer, with a mean arc of flexion of 90 to 140 degrees.^{18,27}
- Free functioning gracilis transfer: El-Gammal et al. report an average arc of elbow flexion of 104 degrees. Elbow flexion power increased an average of 3.8 grades,²⁸ and 79% of patients achieve at least M4 elbow strength.²⁹ Average

passive elbow range of motion significantly decreased from 147 to 117 degrees.²⁸

Forearm Reconstruction

- Biceps rerouting: Rühmann and Hierner reported an average increase in pronation of 87 degrees (range 70 to 100 degrees). Active pronation to neutral was achieved in 91% of patients and 46% were able to pronate 30 degrees or more.³⁰ Results are less favorable in those with limited preoperative passive supination³¹ or active pronation.
- PT release/rerouting: PT release results in approximately 50 degrees of decreased forearm pronation.³² PT rerouting results in an improvement of active supination between 45 and 90 degrees.^{23,33} Over time, there may be attenuation at the insertion site, leading to loss of supination.³⁴

Wrist/Fingers Reconstruction

- FCU to ECRB tendon transfer: Transfer results in an average gain in wrist extension of approximately 47 degrees.³⁵ Al-Qattan¹⁴ reported that average wrist extension muscle strength increased from 0 to 4 on a modified MRC system for motor grading. All patients, regardless of gains in wrist extension, discontinued use of a wrist orthosis.³⁵
- Free functioning gracilis transfer: Terzis and Kostopoulos reported a postoperative mean MRC grade of 3.17 and 4.00 when innervated by the intercostal or spinal accessory nerve, respectively.³⁶ In a series by Chim et al.,²¹ the youngest patients in their series (ages 6 and 8) developed elbow joint flexion contractures. Many patients require secondary procedures to optimize finger flexion and hand function.

COMPLICATIONS

Elbow Reconstruction

- Elbow release: neurovascular injury, weakening of elbow flexion, recurrent contracture
- Steindler flexorplasty: neurovascular injury, nonunion of fusion site, elbow flexion contracture, wrist flexion contracture
- LD transfer: hematoma/seroma, muscle nonfunction or ischemic failure, loss of muscle tension, clavicle fracture, elbow flexion contracture, compartment syndrome

- Free functioning gracilis transfer: neurovascular injury, muscle nonfunction or ischemic failure, clavicle fracture, elbow flexion contracture

Forearm Reconstruction

- Biceps rerouting: neurovascular injury, persistent supination or pronation contracture, tendon rupture
- PT release/rerouting: neurovascular injury, persistent pronation or supination contracture, attenuation of the reinsertion site

Wrist/Fingers Reconstruction

- FCU to ECRB tendon transfer: neurovascular injury, attenuation of the transfer, limited finger release resulting from weak finger extensors or tight finger flexors.
- Free functioning gracilis transfer: neurovascular injury, muscle nonfunction or ischemic failure, adhesions, bowstringing across the elbow, elbow flexion contracture

Section XIV: Lower Extremity

56 Rotationplasty of the Lower Extremity

CHAPTER

Samer Attar, Robert J. Steffner, and Terrance D. Peabody

DEFINITION

- Rotationplasty of the lower extremity is a reliable and durable reconstructive option in the setting of bone loss in the lower extremity due to tumor, infection, or trauma.
- With resection of the bone around the knee joint, the rotated tibia is attached to the remaining femur.
- With appropriate preoperative education and proper patient selection, it is a functional alternative to an above-knee amputation or endoprosthetic reconstruction—especially in the skeletally immature patient.

ANATOMY

- The distal limb is rotated 180 degrees. This technique permits the rotated ankle joint to function as a knee joint for prosthetic fitting (**FIG 1**).
- The stump can fit into a modified below-knee prosthesis that is end-bearing, as opposed to ischial-bearing prostheses for above-knee amputations.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Historically, rotationplasty has been described in the management of femoral bone loss from tuberculosis, proximal femoral focal deficiency, and sarcomas.^{1,2}
- Indications for rotationplasty

- Congenital bone loss or deficiency
- Sarcomas of the lower extremity
- Trauma
- Failed arthroplasty
- Skeletally immature patient or active adult patient
- Contraindications
 - Pre-existing nerve damage or ankle stiffness
 - Sciatic nerve involvement in tumor requiring its resection
- Physical examination
 - The soft tissues proximal and distal to the area of tumor must be intact and free of disease.
 - The ankle joint must be inspected for any contractures or limitations to motion.
 - The dorsalis pedis and posterior tibialis pulses must be inspected for flow.
 - Ankle extension, ankle flexion, and extensor hallucis longus motor strength must be documented.
 - A sensate foot with 5/5 motor strength and full ankle range of motion is ideal.

IMAGING

- Limb lengths of both lower extremities are obtained.
- Bone age should be approximated as the nonoperative limb will continue to grow.
- In malignant bone tumors about the knee undergoing resection, the distal femoral and proximal tibial growth plates are usually removed.
- When the patient reaches skeletal maturity, the rotated tibiotalar joint of the operative limb should be located at the center of rotation of the knee of the nonoperative limb.
- The projection of growth of the nonoperative limb must be taken into consideration at the time of surgery. Therefore, in a skeletally immature individual, the operative leg must be longer than the nonoperative femur.
- In the setting of sarcoma, magnetic resonance imaging determines where to resect the femur with an adequate margin, whether the joint is contaminated, and whether vascular structures are contaminated.
 - If there is joint invasion, an extra-articular resection should be performed.
 - If tumor infiltrates or encases vessels, vascular resection with anastomosis should be considered.

- The tibial and peroneal nerves should be intact and free of disease as they will be required to power ankle motion.

FIG 1 • Limb after rotationplasty, allowing the rotated ankle joint to function as a knee joint for prosthetic fitting.

SURGICAL MANAGEMENT

- Operative intervention must focus on the creation of appropriate flaps, wide resection of bone and soft tissue margins, and stable fixation of the remaining femur to the rotated tibia.

Preoperative Planning

- Extensive discussions with the patient and family are essential prior to performing a rotationplasty. The options of an amputation vs internal prosthesis

must be reviewed in addition to explaining their respective risks/benefits.

- Imaging is reviewed to determine levels of resection of the femur and tibia in order to:
 - Achieve a sound oncologic margin
 - Account for a projected center of rotation of the rotated tibiotalar joint to be at the same level of the nonoperative knee when the patient reaches skeletal maturity

Positioning

- The patient is placed supine on a radiolucent table.
- The entire lower extremity from the pelvis to the foot must be prepped and draped.
- This setup provides vascular access and enables internal fixation to the level of the hip joint if needed.
- Intraoperative fluoroscopy is recommended in order to aid placement of hardware.

Approach

- The skin incision must be planned to accommodate the disproportion between thigh and calf circumference.
- Circumferential incisions are commonly made at acute angles to each other to account for this thigh/calf discrepancy (**FIG 2**).
- A longitudinal incision is then drawn to connect the proximal and distal circumferential flaps. This line is placed ideally to expose a plane for tumor resection and neurovascular dissection.³⁻⁶

FIG 2 • Intraoperative outline of incision in the right lower extremity of a pediatric patient with a distal femur osteosarcoma.

TECHNIQUES

■ Incision

- Skin and subcutaneous tissues are incised and raised as flaps along the circumferential thigh and calf tissues and the longitudinal line connecting them (**TECH FIG 1A,B**).

TECH FIG 1 • **A.** Incision with thick skin flaps. Note the circumferential incisions placed at oblique angles in order to accommodate the difference in thigh and calf diameter during rotation and closure of the wounds. **B.** The rhomboid incision should have an

anterior axis that is about 5 to 10 cm longer than the intended length of the bone resection. The bone resection itself should be located at the proximal and middle thirds of the more proximal incision.

■ Nerves

- The peroneal nerve is identified deep to the biceps tendon coursing laterally around the proximal fibula. It is dissected free of the surrounding soft tissue and followed proximally into the posterior thigh until its bifurcation with the tibial nerve (**TECH FIG 2A**).
- The tibial nerve is traced distally through the popliteal space and distal to the proposed osteotomy site. It is also dissected proximally until the sciatic nerve is identified and traced above the level of the proposed femoral osteotomy.
- Alternatively, the sciatic nerve may be identified proximally and traced distally through its bifurcation into the tibial and peroneal nerves (**TECH FIG 2B**).

TECH FIG 2 • A. The peroneal nerve is dissected more proximally to the location where it joins the tibial nerve at the bifurcation. The tibial nerve can then be dissected distally into the popliteal space. **B.** Sciatic nerve (*arrow*) dissected from surrounding soft tissues.

■ Vessels

- Transection of the pes anserinus and medial gastrocnemius tendons reveals the popliteal artery and vein. They are traced distally to the trifurcation. Proximally, they are delivered posteriorly away from the femur, and the dissection should stop proximal to the proposed femoral osteotomy site.⁷
- The vessels must be free and untethered from all surrounding soft tissues from proximal to distal to prevent kinking and tension when the tibiotalar joint is rotated (**TECH FIG 3**).

- In the setting of vascular involvement with tumor, the vessels can be resected and the remnants anastomosed. However, this technique possesses a higher risk and higher potential for complications.

TECH FIG 3 • Femoral vessels (*arrow*) dissected from surrounding soft tissues.

■ Osteotomies

- Once the neurovascular structures are dissected and freed, attention should be turned to the femoral and tibial osteotomies.
- Steinmann pins can aid in rotation of the limb (**TECH FIG 4A**).
 - Proximal to the level of bone resection, a pin can be placed anterior to posterior with the patella directed straight anteriorly.
 - Distal to the tibial resection, a second pin is placed in the medial tibia perpendicular to the femoral pin.
- The surrounding soft tissues are then incised down to the proposed osteotomy sites.
 - Distally, the patellar tendon, the cruciate and collateral ligaments, the knee menisci, and the posterior knee capsule are incised and released at the level of the tibial insertion.
 - Proximally, the quadriceps, hamstring, and adductor musculature are incised down to the level of the femoral osteotomy site.

TECH FIG 4 • A. Steinman pin placed anterior to posterior in the proximal femur and medial to lateral in the distal tibia. **B.** Intercalary specimen with resected proximal tibia.

- Attention must always be paid to maintaining tumor margin and protecting neurovascular structures during these steps.
- The femur and tibia can then be osteotomized with an oscillating saw, and the specimen is passed off the field (**TECH FIG 4B**).

■ Marrow Margin

- A femoral bone marrow margin should be sent to pathology for a frozen section. It should be confirmed that this margin is negative prior to proceeding with reconstruction.
- During this wait time, the wound can be irrigated. The continuity of the vessels and nerves should be examined and should be tension-free (**TECH FIG 5**).

TECH FIG 5 • Depiction of the limb after extra-articular resection of the distal femur before rotation of the limb.

■ Rotation/Reconstruction

- Reconstruction involves external rotation of the tibia by 180 degrees. If a medial tibial pin was placed, it should be perpendicular to the femoral pin from the lateral direction once rotation is complete (**TECH FIG 6A–C**).
- The vessels and nerves should coil in a relaxed fashion with no excessive tension. Any kinking or tension of neurovascular structures suggests adherent soft tissues that should be released (**TECH FIG 6D–F**).
- The lateral aspect of the femur and medial aspect of the tibia are then exposed to permit compression plating fixation of the femoral-tibial junction. Fixation of six to eight cortices on either side of the junction is ideal if the remaining bone allows. Alternative methods of fixation are intramedullary

rods or external fixators.

- Intraoperative fluoroscopy aids final images documenting limb alignment and positioning of hardware (**TECH FIG 6G,H**).
- Flow to the foot must be documented prior to closure by palpation and/or Doppler ultrasound of the dorsalis pedis and posterior tibialis pulses.

TECH FIG 6 • **A.** Rotation of the distal limb. **B.** Tibial pin (*arrow*) is medial, and the foot is anterior. **C.** When the tibia has been rotated externally, the pin extends from lateral to medial, exactly 180 degrees from its original position. The osteotomy is fixed with a compression plate and screws. The vessels coil

medially. **D.** The neurovascular structures should be relaxed and tension-free. Continuity of the sciatic nerve (*white arrow*) and femoral vessels (*black arrow*). **E.** View of the lower extremity after rotation. **F.** Close-up view of the coiled vessels and nerves (*arrow*). **G.** Intraoperative fluoroscopic radiographs of compression plate fixation between the remaining proximal femur and rotated distal tibia. **H.** AP view. Lateral view.

■ Closure

- Drains are placed per surgeon discretion.
- A layered closure is then performed. The quadriceps fascia is usually sutured to the gastrocnemius musculature and deep fascia of the calf. The hamstring fascia is sutured to the pretibial fascia (**TECH FIG 7**).
- A bulky dressing is ideal to maximize padding and minimize swelling. The internal fixation should be rigid, so no cast is usually needed.

TECH FIG 7 • Extremity after closure and before dressing applied.

Indications	■ Indicated in skeletally immature or active individuals. Preoperative education of the patient and family with literature, photos, and communication with patients who have undergone rotationplasty is beneficial.
Preoperative planning	■ Plan the length of the operative limb so that at skeletal maturity, the rotated tibiotalar joint of the operative limb should be located at the center of rotation of the knee of the nonoperative limb.
Approach	■ Angle circumferential incisions to account for discrepancies in thigh and calf circumference.
Technique	■ Vessels and nerves should be coiled in a relaxed fashion with no tension. ■ Use landmarks or pins to approximate rotation of the tibiotalar joint to 180 degrees. ■ Confirm vascular flow after rotation and fixation.

POSTOPERATIVE CARE

- The status of the limb must be followed closely with frequent neurovascular and compartment checks.
- Mobilization out of bed with assistive devices is encouraged as soon as possible. Active motion of the hip and ankle should be promoted as well.
- If there is a nerve palsy, an ankle-foot orthosis may be placed, and the foot and ankle should be passively ranged to prevent a contracture until motor function returns.
- Adequate wound healing usually occurs in 2 to 6 weeks. At that point, provisional prosthetic fitting may begin. However, no weight bearing through the prosthesis should be allowed until clinical and radiographic healing is evident at the femoral-tibial junction (**FIG 3**).
- Once healing has occurred, activities as tolerated are allowed with a prosthesis.

OUTCOMES

- Rotationplasty provides local recurrence rates comparable to other forms of wide resection such as limb salvage and amputation.
- Gait velocity and the energy cost for mobility are improved compared to a transfemoral amputation.

- Rotationplasty permits participation in recreational and sports activities due to an end-bearing prosthesis, whereas endoprosthetic reconstruction has limitations due to concerns over prosthetic wear and loosening.
- Psychosocial problems due to the cosmetic appearance of a rotated limb are not usually reported.
- Psychosocial issues can be avoided through preoperative education of the patient and family with literature, photographs, and interactions with patients who have had rotationplasties.

FIG 3 • Radiographs of the hip at 6 months postop. **A.** AP view. **B.** Lateral view.

- No adverse events have been reported with regard to the ability to pursue an education or career or develop and maintain relationships.
- There are no phantom pains or neuromas reported due to nerve continuity unlike in amputations.
- Rotationplasty is a reliable, predictable, and durable reconstructive option in the active or skeletally immature patient with a malignant bone tumor about the knee. Functionally, it can be equivalent or better than a transfemoral amputation, and it has comparable oncologic outcomes.^{8–16}

COMPLICATIONS

- Ischemia and vascular compromise can occur—especially in the setting of

vascular resection with anastomosis.

- Transient or permanent nerve palsy can lead to soft tissue contractures or a delay in rehabilitation with a prosthesis.
- Delayed or incomplete wound healing may require debridement with soft tissue coverage.
- Infection.
- Fracture nonunion.
- Hardware failure.
- Compartment syndrome.
- Rotational malalignment.

CHAPTER Poland Syndrome

Patrick J. Buchanan and Paul S. Cederna

DEFINITION

- Poland syndrome is a developmental defect characterized by varying degrees of unilateral pectoralis major aplasia, thoracic skeletal defects, breast hypoplasia or aplasia, and ipsilateral syndactyly.^{1,2}
- A congenital unilateral absence of the sternocostal head of the pectoralis major muscle is pathognomonic for this congenital anomaly.

ANATOMY

- There are two predominant variations of Poland syndrome: simple form (mild) and complex form (severe).
- The simple form is the most common and is characterized by the absence of the sternocostal head of the pectoralis major muscle and effacement of the ipsilateral axillary fold.
 - The clavicular head of the pectoralis major muscle remains as a thin triangular muscle bundle that attaches the humerus to the inferomedial third of the clavicle.
 - The ipsilateral breast is hypoplastic or aplastic.
 - The ipsilateral nipple-areolar complex is typically smaller in diameter and displaced laterally and superiorly toward the axilla (**FIG 1**).
- The complex form is characterized by the absence of the sternocostal head of the pectoralis major muscle, ipsilateral rib and/or sternal hypoplasia or absence, and other ipsilateral muscular abnormalities (**FIG 2**).
 - The clavicular head of the pectoralis major muscle may be diminutive.
 - The ipsilateral latissimus dorsi, trapezius, pectoralis minor, serratus anterior, external oblique, and/or rectus abdominis muscles may be abnormal.

- The pectoralis minor muscle is commonly hypertrophic.
- Absence of the serratus anterior muscle results in a winged scapula.

FIG 1 • Simple form of Poland syndrome depicting an ipsilateral breast anomaly with a smaller and superolaterally displaced nipple-areolar complex.

- Insertion of the ipsilateral rectus abdominis muscle is displaced cranially.
- The sternum is foreshortened and bifid with a pectus excavatum appearance.
- The ipsilateral scapula is small and cranially displaced, causing an internal shoulder rotation when compared to the contralateral side.
- The ipsilateral anterior second through fifth ribs are thin, short, and devoid of their superolateral cartilage.

PATHOGENESIS

- To date, no definitive cause of Poland syndrome has been elucidated.
- However, there are theories identifying developmental and familial causes.
 - Developmentally, in the 6th week of gestation, there is an interruption of the subclavicular arterial branches causing maldevelopment of the tissues supplied by these vascular pedicles
 - Currently, geneticists believe Poland syndrome is rarely inherited; however, there is documentation of a 1% inheritance pattern from affected individuals.

NATURAL HISTORY

- The true incidence and etiology of Poland syndrome still remains unknown; however, it tends to occur more on the right side, 2 to 3:1, is more common in

males, 2:1, and is estimated to occur 1 in 20 000 to 30 000 live births.³

- The most common presentation is that of a patient with a unilateral absence of the sternocostal head of the pectoralis major muscle with hypoplastic or absent breast parenchyma.¹

FIG 2 • Complex form of Poland syndrome showing ipsilateral axillary webbing, ipsilateral rib and sternal hypoplasia, ipsilateral trapezius, serratus anterior, rectus abdominis, and external oblique muscle abnormalities.

- The vast majority of patients with Poland syndrome present with concerns about the shape and appearance of their chest or abnormal breast development.¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- The surgeon must be acutely aware of the social impact of Poland syndrome on the patient and their parents.
- Patients with the simple form of Poland syndrome may be aware of their abnormality earlier than their family, as it can remain unannounced until early adolescence, as muscle and breast development occur.
 - Early in childhood, parents may notice a slight chest asymmetry.
 - Adolescent children with Poland syndrome spend an inordinate amount of time trying to conceal their asymmetry from their parents and others.
- The severe form, on the contrary, is readily known during infancy by the parents, as the chest wall is grossly asymmetric.

- In all patients, there will be a noticeable soft tissue deficiency of the affected side of the chest due to volume loss from the partial or complete absence of the pectoralis musculature.
- The noticeable asymmetry often leads to adverse psychosocial sequelae.
- Patients often report an adverse impact on their social functioning, emotional well-being, and psychological health.

IMAGING

- Diagnostic imaging is available but usually not necessary in cases other than the most severe variants.
- Ultrasonography will show an absence of a portion of the pectoralis major muscle and asymmetry of the rib cage.⁴
- Mammography is typically not used as an imaging modality for Poland syndrome; however, absence of the pectoralis major muscle can be incidentally discovered on the mediolateral oblique view of a hypoplastic breast.⁴
- A CT scan can be used for presurgical planning to confirm the presence of the latissimus dorsi muscle and to better define the structural chest wall deformity.⁵
- MRI may be useful to better define the patient's anatomy as it offers a multiplanar view without the ionizing radiation of a CT scan.⁵
- Both color-coded duplex sonography and contrast-enhanced magnetic resonance angiography allow for the evaluation of selected arteries and vessels.⁵

DIFFERENTIAL DIAGNOSIS

- Unilateral accentuated thelarche
- Unilateral amazia
- Unilateral amastia

NONOPERATIVE MANAGEMENT

- Because reconstruction is rarely ever performed to restore a severe functional deficit, providing reassurance to the patient and their family is an important aspect of care that should not be overlooked by the surgeon.
- Removable external breast prostheses help correct the appearance of a female patient's chest and breast in clothing.

SURGICAL MANAGEMENT

- The reconstructive options for patients presenting with chest wall deformities from Poland syndrome depend on several key factors, including anatomical severity, gender, patient preferences, and associated anomalies.
- The timing and number of reconstructive stages is also of paramount importance.
 - A tissue expander can be placed early to gradually expand the affected side to decrease the amount of noticeable asymmetry as the contralateral breast developmentally matures.
 - Fat grafting can be initiated early to camouflage the asymmetry until the definitive reconstructive procedures are performed.
- Tissue expander-based reconstruction is ideal for the female patient with a hypoplastic and fibrotic breast or a patient with an aplastic breast.
- The latissimus dorsi muscle transfer can be used with any of the reconstructive approaches.
 - It is the best method to reconstruct the anterior axillary fold.
 - It can be performed on any patients, male or female, with a robust latissimus dorsi muscle.
 - The surgeon should discuss with the patients that harvesting of the latissimus dorsi muscle can create asymmetry in their back.
- Customized chest wall implants may be adjunctively needed in women and are often the treatment of choice in men.⁶
 - Author preference is for a custom silicone chest wall prosthesis.
 - The advantages of the customized chest wall implant reside in its ease of fabrication and insertion.
 - There is a relatively low morbidity for this technique compared to flap reconstruction.⁶
 - Disadvantages include implant migration, contour irregularities, patient reported discomfort, and potentially palpable or visible edges.⁶
- The endoscopic approach is typically performed in two stages when using a tissue expander and latissimus dorsi muscle transfer

Preoperative Planning

- Documenting the presence or absence of the serratus anterior and latissimus dorsi muscles is necessary, because this may affect desired reconstruction.
- The degree of pectoralis major muscle hypoplasia is also critical to determining the most appropriate reconstructive option for the patient.

- The sternal notch-to-acromion, acromion-to-olecranon, and olecranon-to-ulnar styloid distances are measured and compared to the contralateral side, in cases of notable skeletal abnormality.
- In women, the size of the breast and position of the nipple complex are assessed, particularly in regard to the contralateral, normal side.
- In the occasional male who seeks muscular strength improvement due to absence of the pectoralis musculature, objective testing of strength of the upper extremity via comparison to the contralateral side is needed.¹
- Male patients often lift weights in an attempt to increase the bulk of their affected chest.
- Weight lifting typically causes the pectoralis minor and the clavicular head of the pectoralis major muscle to become more hypertrophic (**FIG 3**).

FIG 3 • Male patient with Poland syndrome showing hypertrophy of the ipsilateral pectoralis minor and clavicular head of the pectoralis major muscles.

Positioning

- The traditional latissimus dorsi muscle transfer harvest is performed by positioning the patient in a semilateral decubitus position with the ipsilateral arm elevated on an arm sling.
- **TECH FIG 1A** shows the intraoperative positioning for muscle harvest.
- **TECH FIG 1B** depicts the large incisional scar that can be expected from this traditional approach.
- Alternatively, the latissimus dorsi muscle harvest and implant placement can be performed via a single axillary incision with the patient's ipsilateral arm

extended cranially.

Approach

- Reconstructive options include the use of tissue expansion with implants, latissimus dorsi muscle transfers, customized chest wall implants, fat grafting, and rarely, free tissue transfers.^{1,7–10}
- Frequently, contralateral procedures are performed after definitive reconstruction of the affected side to achieve better symmetry.
- Symmetry procedures include, but are not limited to, contralateral breast reduction, mastopexy, repositioning of the nipple-areolar complex (NAC), and reducing the size of the NAC.
- Both implant-based and latissimus dorsi muscle transfer reconstructions can be performed with an endoscopic approach to minimize scarring.⁷

TECHNIQUES

■ Tissue Expansion with Implants

- The fibrotic breast tissue requires radial scoring prior to tissue expander placement to allow for adequate expansion.¹¹
- The degree of muscle coverage of the expander is dependent on the extent of pectoralis major muscle absence.
 - Partial superior coverage will be achievable in some patients.
 - Subglandular or subcutaneous placement is necessary when the pectoralis major muscle is notably hypoplastic or fully absent.
- Expansion is performed as necessary, followed by permanent implant placement, similar to breast reconstruction.
 - This technique can be performed in stages separated by many years.
 - The tissue expander can be placed early to allow for gradual expansion as the contralateral breast grows, prior to permanent implant placement.

■ Latissimus Dorsi Muscle Transfer

- Most often, a skin paddle is not required and, as such, a single incision can be used.

- A dorsal incision above the lateral border of the latissimus dorsi muscle, approximately 6 to 10 cm long, is one option to gain access to the muscle^{12,13} (see **TECH FIG 1A,B**).
- An endoscope can also be used to gain access to the muscle with a single, 5- to 6-cm incision placed within the axilla⁷ (**TECH FIG 1C**).
- The skin/soft tissue is elevated off of the fascia overlying the latissimus muscle to expose the borders of the entire muscle. The muscle is divided distally and the fascial and muscular attachments to the chest wall are divided, elevating the muscle toward the axilla^{12,13} (see **TECH FIG 1**).

TECH FIG 1 • **A.** Traditional open approach to latissimus dorsi muscle harvest with the patient positioned in a lateral decubitus with the ipsilateral arm extended at 90 degrees on an operative armrest. **B.** Surgical scar created after a traditional, open harvest of the latissimus dorsi muscle for Poland syndrome reconstruction. **C.** Endoscopic approach with the patient in a supine position and the ipsilateral arm extended at 90 degrees allowing for a 5- to 6-cm incision placed within the apex of the axilla.

- The ipsilateral chest skin is undermined through the axillary incision or through a periareolar approach.
- The chest and previous axillary dissection planes are then joined.
- The mobilized latissimus dorsi muscle is then transferred.
- Release the insertion of the latissimus dorsi muscle and suture it anteriorly near the bicipital groove, on the humerus, to recreate the anterior axillary fold.
- The origin, lumbosacral fascia, is affixed to the lateral border of the sternum.

- Care must be taken to preserve the innervation to minimize the amount of muscle atrophy over time.

■ Customized Chest Wall Implants

- The entire operation, with implantation, can be performed through a single 4-cm incision.
- A malleable custom silicone chest wall prosthesis is positioned using endoscopic techniques (**TECH FIG 2**).

TECH FIG 2 • Customized chest wall implant insertion using the endoscopic approach with a single 4-cm incision.

■ Endoscopic Approach

- First stage⁷:
 - The patient is positioned supine, and a 5- to 6-cm incision is placed in the apex of the axilla (see **TECH FIG 1C**).
 - The dissection is performed in the subcutaneous plane to expose the border of the clavicular head of the pectoralis major muscle.
 - A 10-mm, 30-degree endoscope is attached to an endoretractor and placed within the dissected pocket to extend it medially to the sternum and inferiorly to the proposed inframammary fold.
 - Once this pocket is developed, a tissue expander is then placed.
- Second stage occurs once the tissue expander is expanded to its desired

volume and the patient has reached his or her full developmental maturity.⁷

- Performed in the lateral decubitus position.
- The same 5- to 6-cm incision is used for the harvest of the latissimus dorsi muscle.
- The 10-mm, 30-degree endoscope is inserted to complete the superficial and deep dissection of the latissimus dorsi muscle as previously described (**TECH FIG 3**).
- With the thoracodorsal neurovascular pedicle directly visualized, the origin and insertion of the muscle are divided.
- The patient is then repositioned supine, and the anterior dissection is performed to regain access to the tissue expander.
- The tissue expander is removed and the latissimus dorsi muscle is transferred into the anterior pocket and sutured into place.
 - The lumbosacral fascia is affixed to the sternum and along the new position of the inframammary fold.
 - The former lateral border of the latissimus dorsi muscle is secured to the inferior border of the clavicular head of the pectoralis major muscle.

TECH FIG 3 • Two-stage endoscopic approach using a 5-cm axillary incision. The initial dissection is performed under direct, open, visualization. The subsequent dissection is performed under endoscopic visualization for muscle harvest.

- The insertion of the latissimus dorsi muscle is attached anteriorly to the bicipital groove of the humerus.
 - A breast implant can then be positioned deep to the latissimus dorsi muscle.
-

PEARLS AND PITFALLS

Hemostasis	■ Maintain adequate hemostasis to avoid hematomas that may subsequently become infected causing removal of implants.
Latissimus dorsi muscle transfer	■ Avoid dissecting under the teres major at the inferior angle of the scapula. ■ Maintain visualization of the thoracodorsal pedicle during the endoscopic harvest of the latissimus dorsi muscle to avoid injury to the pedicle. ■ Perform dissection of the vascular pedicle under direct visualization in the axilla to permit safe mobilization of the latissimus dorsi muscle.
Tissue expander and implant	■ Score the deep surface of the breast parenchyma to allow complete expansion of the breast.
Customized chest implants	■ Paying special attention to “feathering” of the implant’s border during design and fabrication of the implant can hide visible, palpable edges (FIG 4). ■ Fat grafting during implantation can also help reduce visible and palpable edges. ■ Fat grafting can also be done secondarily to correct visible and palpable edges noted postimplantation.
Secondary procedures	■ Often contralateral mammoplasty is needed to maintain symmetry. ■ Nipple-areolar complex reconstruction is occasionally needed. ■ Translocation of the nipple-areolar complex to create symmetry with the contralateral side may be indicated.

POSTOPERATIVE CARE

- Following Poland syndrome reconstruction, standard incisional postoperative care is required.
- For patients who require an implant-based reconstruction, postoperative protocols apply.
 - Perioperative oral antibiotics are commonly given.
 - Closed-suction drains, when placed, are not removed until the output from each drain is less than 30 cc for 2 consecutive days.

OUTCOMES

- The goals for reconstruction of the female patient are to achieve breast symmetry, recreate the anterior axillary fold, and provide adequate infraclavicular fullness.
- These goals are successfully achieved with any of the aforementioned reconstructive options.
- To optimize breast symmetry, female patients most often request a contralateral mastopexy and/or reduction.
- Seyfer et al.¹⁴ performed 57 operations on 29 women and incurred no revision operations when they performed the latissimus dorsi transfer in conjunction with breast implant. Most complications seen were due to the breast implant itself. Capsular contractures were revised using open capsulotomies.¹⁴
- The general goal for reconstruction of the male patient is to achieve symmetric chest wall contour (**FIG 4**).
- As in their female counterpart, the latissimus dorsi transfer had better overall outcomes.³
- When performed as an isolated procedure, the latissimus dorsi muscle transfer is prone to undercorrect the deformity; however, fat grafting can be used as an adjunctive procedure to improve symmetry over time.
- The reconstructive results for Poland syndrome tend to be long-lasting, accompanied by high patient satisfaction.³

COMPLICATIONS

- Complications of Poland syndrome reconstruction include seroma, hematoma, infection, scar, delayed wound healing, and pain/paresthesias.
- Seroma formation was most often seen after the removal of the closed-suction drains in the latissimus dorsi transfer donor site.¹⁴
- However, as in the Seyfer et al.¹⁴ study, these seromas are typically small and treated conservatively until they resolve on their own.
- Long-term complications can occur with implant-based reconstruction and are manifested predominantly by capsular contracture and implant rupture.^{3,14}
- Progressive asymmetries can also become apparent over time due to discordant amount of breast tissue and differences in the skin envelope.
- Implant infection and malposition may also occur.

FIG 4 • Left Poland Syndrome. **A.** Preoperative. **B.** Four years postoperative using a customized chest wall implant reconstruction with a “feathering” technique to camouflage the edges of the implant.

CHAPTER Gynecomastia

Dennis Hammond and Eric Yu Kit Li

DEFINITION

- Gynecomastia involves the abnormal proliferation of glandular breast tissue in men, resulting in breast enlargement.^{1,2}
- It is distinguished from pseudogynecomastia or lipomastia, which is characterized by fatty deposition without glandular development.

ANATOMY

- In healthy patients, the male breast resembles that of a prepubescent female.
- Fat is the predominant tissue and lobules are absent, in contrast to ductal and lobular development in females (**FIG 1**).
- The ideal male breast is also flat, to accentuate the contour of the underlying pectoralis major muscle.
- The arterial supply, venous drainage, lymphatic drainage, and sensory supply mimic those of the female breast.
- Although there is general consensus on the ideal size, shape, and location of the nipple-areolar complex (NAC) in women, this subject has been less extensively studied in men.
- Various authors have published equations to calculate the ideal NAC on the male torso, often as a function of measurements such as patient height and chest circumference.³⁻⁸
- Some general themes exist among the various formulas, in that the ideal male NAC is
 - Slightly oval (horizontal greater than vertical)
 - Smaller (with diameter lesser than 3 cm)

- Positioned around the 4th or 5th intercostal space
- Recent studies have characterized the shape of gynecomastia specimens as having a head, body, and tail^{9,10} (**FIG 2**).
 - The head is semicircular in shape and extends toward the midline.
 - The body is located directly underneath the NAC and intimately attached to it.
 - The tail tapers off and extends toward the axilla.
 - Awareness of this shape may help guide intraoperative dissection.

PATHOGENESIS

- Gynecomastia occurs due to a hormonal imbalance between the level or action of estrogens and androgens.^{1,2}
 - Estrogens stimulate breast development, whereas androgens inhibit it.
- Causes of this imbalance may be idiopathic, physiologic, pharmacologic, or pathologic.¹¹

FIG 1 • In the normal male breast, fat is the predominant tissue and lobules are absent. This is in contrast to the developed female breast, which features lobules and ducts.

FIG 2 • A typical gynecomastia specimen with head, body, and tail sections.

- Obesity is also strongly associated with gynecomastia, due to increased levels of circulating estrogens from peripheral aromatization of androgens in adipose tissue.¹
- Histopathologically, early-stage gynecomastia is characterized by ductal proliferation with loose stromal tissue (florid type).¹²
- Over time, generally over the course of a year, the stromal tissue undergoes fibrosis (fibrotic type).¹²
- Gynecomastia that has undergone fibrosis is unlikely to be responsive to medical treatment.

NATURAL HISTORY^{1,2}

- Physiologic gynecomastia (**FIG 3A–C**)

- Often seen in newborns, adolescents, and older men
- Adolescent gynecomastia:
 - May begin as early as age 12
 - Can occur in up to 65% of adolescent boys¹³
 - Breast enlargement typically lasts 6 to 12 months.
 - Ninety percent of cases spontaneously resolve without treatment.¹⁴
 - Generally, presents as a subareolar, firm, concentric, fibrous mass with surrounding fibrofatty tissue that is proportional to the body habitus of the patient
- Senescent gynecomastia (**FIG 3D**):
 - Can occur in up to 65% of men over 65 years of age¹⁵
 - Generally presents as diffuse fibrofatty tissue that gradually enlarges over time
- Pathologic gynecomastia
 - Can occur at any age, related to a tumor or medical condition (eg, liver or kidney disease)
 - There may be a history of rapid eccentric growth, nipple discharge, skin changes, or constitutional symptoms.¹²
- Pharmacologic gynecomastia
 - Can occur at any age, related to a drug exposure.
 - Generally presents as a subareolar, firm, concentric, mass.
 - If the mass is not fibrotic, stopping the offending medication may resolve the condition.
 - If the mass is fibrotic, stopping the offending medication may halt progression of gynecomastia, but it is unlikely to reduce the breast enlargement already present.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with the suspected diagnosis should be evaluated for both signs and symptoms related to the abnormal breast growth.
- A detailed history should inquire about:
 - The onset and velocity of breast growth
 - The onset of puberty and ongoing pubertal development (if applicable)
 - Any tendency for spontaneous resolution of the breast hypertrophy
 - Associated symptoms, including pain, tenderness, weight loss, night sweats, and general malaise

FIG 3 • A–C. Frontal and lateral views of a 24-year-old man who presented with bilateral physiologic gynecomastia. Both sides were characterized by a subareolar fibrous mass and surrounding fibrofatty tissues. **D.** Frontal view of a 52-year-old man who presented with bilateral senescent gynecomastia with skin excess and NAC ptosis. Both sides were characterized by diffuse fibrofatty tissues.

- Any social, vocational, or avocational dysfunction due to the breast enlargement
- The effect of the breasts on the patient's psychological well-being and self-esteem
- Any personal or family history of breast cancer or disorders
- Medication history, especially recreational and off-the-counter drugs (eg, marijuana and exogenous steroids)
- Symptoms suggestive of underlying thyroid, liver, or kidney disease
- A detailed physical should examine
 - The patient's height, weight, and body mass index
 - For the development of secondary sexual characteristics (if applicable)
 - For the presence of a subareolar mass and its area of involvement
 - For the presence of fibrofatty tissue and its area of involvement

- For other masses, irregularities, or deformities involving the breasts or chest wall
- Overall breast aesthetics, including the shape, size, and symmetry of the breasts and NACs, the degree of ptosis, excess skin, and the position and symmetry of the inframammary folds (IMFs)
- Standard breast measurements to highlight asymmetries, including the sternal notch to nipple, midclavicular to nipple, nipple to midline, and nipple to IMF distances
- The patient's neck, abdomen, and testicles for any masses or irregularities

IMAGING

- Imaging is not typically required if the history and physical examination are consistent with physiologic gynecomastia.
- In suspected cases of pathologic gynecomastia, appropriate imaging (mammogram, ultrasound, etc.) should be carried out based on the identified or suspected abnormalities.

DIFFERENTIAL DIAGNOSIS

- Idiopathic gynecomastia
- Physiologic gynecomastia
- Pseudogynecomastia or lipomastia
- Benign breast tumors (eg, fibroadenoma, giant fibroadenoma, phyllodes tumor, lipoma, or cysts)
- Malignant breast tumors (eg, ductal or lobular carcinoma, lymphoma, or metastases)

NONOPERATIVE MANAGEMENT

- Patient reassurance is the foremost treatment in adolescent gynecomastia.
 - About 90% of adolescent cases spontaneously resolve, so no treatment may be needed at all.¹⁴
 - Treatment is indicated when gynecomastia has persisted for more than 2 years, or if there are overriding functional, medical, or psychosocial concerns that warrant earlier intervention.¹⁶
- In gynecomastia related to reversible etiologies, the offending medication should be stopped or the underlying condition treated as soon as possible.
- Weight loss through dietary restriction and exercise are important first-line treatments in any gynecomastia related to obesity.

- Pharmacologic therapies, including danazol, tamoxifen, and anastrozole, may be effective in preventing or treating early-stage gynecomastia but are less effective once breast tissues undergo fibrosis.²
 - Of these medications, tamoxifen is most widely used, but there are no clear guidelines on the ideal dose or duration.
 - All medications also have unfavorable side effects that must be considered.
- If pathologic gynecomastia is suspected, patients should be urgently referred to the appropriate specialist(s).

SURGICAL MANAGEMENT

- Surgical treatment is indicated when gynecomastia is persistent or causes functional or aesthetic concerns.
- Options include liposuction, excision of the subareolar fibrous tissue, or a combination of the two.
- In patients with significant breast enlargement with skin excess and ptosis, mastopexy may be incorporated as well.
- Although weight loss should be the first-line strategy in any obese patient with gynecomastia, it is still reasonable to proceed with surgery in obese patients since normalizing the chest wall contour may allow the patient to lead a more active lifestyle.¹⁶
- Whether resected gynecomastia tissues should be routinely sent for histopathological examination is debatable.
 - The likely risk of finding occult malignancy in gynecomastia specimens is less than 0.01%.^{12,17}
 - Of note, the College of American Pathologists does not specifically require the use of cancer protocols for gynecomastia, nor do they offer any formal guidelines for the examination of gynecomastia tissue.

Preoperative Planning

- The patient is seen preoperatively 1 to 3 days before surgery to achieve several objectives:
 - To review the procedure in detail, and revisit goals and expectations of surgery with the patient
 - To complete all perioperative paperwork, including orders, prescriptions, and instruction sheets
 - To mark the patient in an unrushed, quiet, and controlled environment
 - To obtain preoperative photographs of the marked patient

- For all procedures, the patient is marked in a standing position with arms at the sides.
 - Preoperative markings are done with a variety of colored markers.
- A laser leveler can be used to confirm the horizontal plane across the chest.
- Preoperative photographs serve several functions:
 - They document the surgical plan electronically.
 - They can be brought to the operating room to guide intraoperative decision-making.
 - They can be compared to postoperative photographs to critically appraise surgical technique and final results.
 - They can be used to educate patients in the preoperative and postoperative settings.
- Photographs, at the minimum, should capture three standard views of the breasts including the front and each side.
 - Supplemental views, including ¾s, hands over head, and with breasts lifted by the patient, can also be taken.
 - Patients should be framed from the top of the shoulders to midway between the breast and umbilicus, with the width extending just outside the arms.

Positioning

- The patient is positioned supine on an operating room table that is capable of sitting up 90 degrees.
 - This positioning will allow the patient to be placed upright intraoperatively and the chest to be evaluated in the sitting position, which may guide intraoperative decision-making.
- The patient's head is positioned at the top of the table, supported by a foam headrest.
- The patient's arms are placed on arm boards and secured to allow safe upright positioning of the patient.
 - Arm boards are placed at the shoulder level.
 - Foam pads are placed between the arm and arm boards.
 - The arm is then secured to both with a soft towel followed by a gentle circumferential wrap of gauze, which runs from the axilla to the hand to provide a uniform layer of support.
- The patient's knees are elevated with a pillow to relieve pressure on the back while the patient is upright, and the patient's heels are supported with foam

pads.

- A heated air-warming device is placed on the lower body.
- The area from the top of the shoulders to midway between the inferior pole of the breast and umbilicus is prepped and draped to allow full visualization of the shoulders, chest, and breasts during surgery.

Approach

- All surgical techniques can be performed under local anesthesia, intravenous sedation, or general anesthesia.
- Development of a surgical plan is based on the need to address two issues.¹⁶
 - How to best remove the excess volume
 - When and how to best remove the excess skin
- Volume reduction techniques:
 - Direct glandular excision is performed when gynecomastia presents as an isolated subareolar fibrous mass.
 - Liposuction is performed when gynecomastia presents largely as a diffuse accumulation of fibrofatty tissue.
 - When both a subareolar fibrous mass and diffuse fibrofatty tissue are present, both direct excision and liposuction techniques are used to effectively recontour the chest wall.
- Skin reduction techniques:
 - In general, most patients do not require skin envelope excision after volume reduction, because the propensity of the chest wall skin to retract is significant, especially in younger patients.
 - Only in cases of significant skin excess or laxity is a skin-reducing procedure required.
 - Small localized areas of skin excess can be directly treated with skin excision.
 - Small reductions in the skin envelope or ptotic NACs can be treated with periareolar mastopexies.
 - Large reductions in the skin envelope or extremely ptotic NACs can be treated with circumvertical mastopexies.

TECHNIQUES

■ Direct Excision

- Landmarks:
 - The patient is marked in a standing position with arms at the sides.
 - The subareolar mass underneath the NAC is palpated and outlined with a surgical marker.
 - The planned incision on the inferior areolar border is marked.
- The planned incision on the inferior areolar border is first infiltrated with local anesthetic.
- Local anesthetic is also injected deep to the NAC and in the subcutaneous tissues overlying the fibrous mass.
 - In this fashion, the plane between the subcutaneous and glandular tissues is intentionally hydrodissected to facilitate later dissection with cautery.
- Using a no. 15 blade, the periareolar incision is made through the deep dermis.
- A Senn retractor is then placed on the dermal edge, upward traction is applied, and the plane between the deep dermis and glandular tissue is carefully dissected with monopolar cautery (**TECH FIG 1A**).
- The dissection is performed both medial and lateral to the area underneath the nipple first (where a true plane exists) and then joined in the middle transecting the ducts (where no true plane exists).
 - Care is taken to ensure that the NAC maintains a uniform thickness of 5 to 10 mm.
- Once beyond the boundaries of the NAC, the dissection is continued with monopolar cautery in the plane between the subcutaneous and glandular tissues, peripherally in all directions.
 - It is important to stay in this plane to preserve the overlying subcutaneous fat and maintain an even contour to the breast skin flaps.
- Once the fibrous mass is freed to its peripheral margins, it is elevated from the pectoralis major fascia.
 - Extra care is taken to avoid violating the fascia.
 - If possible, leave a bed of fat above the fascia to avoid a “saucer” contour deformity deep to the NAC.

TECH FIG 1 • A. The plane between the dermis and glandular tissues. **B.** The completed inferior areolar closure. The gynecomastia specimen is shown above.

- After the fibrous tissue is removed, the chest wall is carefully palpated and inspected for any remaining contour irregularities.
 - Further scissor dissection or cautery excision can be done at this point to feather the peripheral contours and excise any remaining glandular tissue.
- The dissected space is irrigated with normal saline and hemostasis checked.
- The wound layers are closed with 4-0 Monocryl (Ethicon Inc., Somerville, NJ, USA) or equivalent absorbable monofilament dermal interrupted suture, followed by a 3-0 Stratafix (Ethicon Inc., Somerville, NJ, USA) or equivalent absorbable barbed subcuticular suture (**TECH FIG 1B**).
- Dermabond (Ethicon Inc., Somerville, NJ, USA) is lastly applied to the skin incision.

■ Liposuction

- Landmarks:
 - The patient is marked in a standing position with arms at the sides.
 - The fibrofatty issues surrounding the breast are palpated and outlined for liposuction (**TECH FIG 2A**).
 - The planned access incisions for liposuction are marked at the lower border of the NAC and/or along the lateral aspect of the IMF.
 - The planned incisions are infiltrated with local anesthetic.
 - Wetting solution is next infiltrated deep to the NAC and in the surrounding

areas of fibrofatty tissue.

- Typical wetting solution consists of 40 to 60 mL of 1% lidocaine with 1 amp of Epi added to 1 L of NS.
- Fluid is added to each breast until the tissue consistency is firm.
- After allowing time for the wetting solution to take effect, standard liposuction is performed (**TECH FIG 2B**).
- A 3- to 4-mm cannula is used by the author.
- Care is taken to feather the boundaries of the marked areas.
- In bilateral cases, the access incision on the opposite NAC can be used and the cannula passed across the midline to liposuction the subareolar area (**TECH FIG 2C**).
- Underneath the NAC, external pinching compression with the opposite hand is used to drive the dense subareolar fat into the cannula.
- In breasts with a well-defined IMF, the cannula can be used to discontinuously undermine it and soften it.
- All wounds are closed with dermal 4-0 Monocryl (Ethicon Inc., Somerville, NJ, USA) or equivalent absorbable monofilament dermal interrupted suture, and Dermabond (Ethicon Inc., Somerville, NJ, USA) is applied to the skin.

TECH FIG 2 • A. Preoperative markings of the

fibrofatty tissue surrounding the breast and the planned area of liposuction. **B.** The path of the liposuction cannula to reach all areas of the breast. In bilateral cases, the NAC access incision can be used to pass the cannula across the midline to liposuction the opposite subareolar area. **C.** The liposuction cannula is shown passing through the NAC access incision and across the midline to reach the opposite subareolar area.

■ Combination Technique

- Landmarks:
 - The patient is marked in a standing position with arms at the sides.
 - The subareolar mass underneath the NAC is palpated and outlined with a surgical marker.
 - The fibrofatty issues surrounding the breast are palpated and outlined for liposuction.
 - The planned incisions on the inferior areolar border and/or the lateral aspect of the IMF are marked.
- The planned incisions on the inferior areolar border and lateral IMF are first infiltrated with local anesthetic.
- Local anesthetic is also injected deep to the NAC and in the subcutaneous tissue overlying the fibrous mass.
- Wetting solution is then infiltrated into the surrounding areas of the fibrofatty tissue until the breast is firm.
- After allowing time for the wetting solution to take effect, liposuction is then performed using a 3- to 4-mm cannula, as described above.
- Once no further liposuction can be performed, the mass effect of the remaining fibrous portion is assessed.
- If there remains a persistent and protuberant fibrous mass, the inferior areolar border is incised and the glandular tissue excised via direct excision, based on the technique as described above.

■ Periareolar Skin Reduction

■ Landmarks:

- The patient is marked in a standing position with arms at the sides.
- The midsternal line, IMF, and lateral breast contour are marked.
- The top of the periareolar incision is drawn, and symmetry on both sides is confirmed with a laser leveler.
 - The author typically positions the new NAC 2 to 3 cm above the existing IMF.
- A circular pattern is next drawn around the NAC (**TECH FIG 3A**).
- Under maximum stretch, the NAC is outlined with a nipple marker with a maximum diameter of 3 cm.
- Local anesthetic is injected in the deep dermis of the periareolar pattern.
- Wetting solution is also infiltrated deep to the NAC and in the surrounding areas of fibrofatty tissue.
- Liposuction and/or direct excision is first carried out, as described above.
- The breast is accessed through an incision on the caudal portion of the periareolar pattern.
- The NAC is incised to the deep dermis, and the previously marked periareolar pattern preliminarily stapled.
- The patient is then placed upright to visualize the resultant breast shape, and the staple line is adjusted as needed to create the desired chest contour and NAC elevation.
- After the staple line is deemed satisfactory, the patient is returned supine.
- The staple line is marked with a surgical marker, and the staples are removed.
- The intervening skin within the periareolar pattern is then de-epithelialized.
- Typically, the periareolar dermis is minimally incised or not incised at all to maintain the subdermal plexus that supplies the NAC.
- The dermis may be incised, however, in staged scenarios in which the NAC has secondarily revascularized via its wound base.
- The periareolar defect is lastly closed using a periareolar purse-string technique.¹⁸
 - Eight evenly spaced cardinal points are marked on the areola and periareolar incision.
- A 2-0 Cytoplast (Surgiform Technologies Ltd., Columbia, SC, USA) or

equivalent polytetrafluoroethylene (PTFE) suture on a straight needle is selected.

TECH FIG 3 • A. A circular pattern is drawn around the NAC to outline the periareolar pattern. **B.** Appearance of the periareolar pattern after weaving of the purse-string suture. **C.** The completed periareolar closure.

- The suture is then passed, from deep to superficial, starting on the medial dermal shelf of the periareolar incision, through the corresponding cardinal point on the dermis of the areola, inserted back into the outer dermal shelf, and then passed through the periareolar dermis to the next cardinal point.
- This weaving is continued until the suture has weaved completely around the periareolar defect, culminating in the appearance of a wagon wheel (**TECH FIG 3B**).
- The free suture ends are then tightened to cinch the periareolar incision down to match the diameter of the areola, followed by placement of 8 to 10 square knots to secure the suture.

- The knot complex is placed underneath the medial dermal shelf, and the periareolar closure is completed with 3-0 Stratafix or equivalent absorbable barbed suture (Ethicon Inc., Somerville, NJ, USA) (**TECH FIG 3C**).

■ Circumvertical Skin Reduction

- Landmarks:
 - The patient is marked in a standing position with arms at the sides.
 - The midsternal line, IMF, and lateral breast contour are marked.
 - The top of the periareolar incision is drawn, and symmetry on both sides is confirmed with a laser leveler.
 - The author typically positions the new NAC 2 to 3 cm above the existing IMF.
 - A circular pattern is next drawn around the NAC, followed by a vertical pattern below the NAC extending in a curvilinear fashion toward the IMF (**TECH FIG 4**).
 - Under maximum stretch, the NAC is outlined with a nipple marker with a maximum diameter of 3 cm.
- Local anesthetic is injected in the deep dermis of the periareolar pattern.
- Wetting solution is also infiltrated deep to the NAC and in the surrounding areas of fibrofatty tissue.
- Liposuction and/or direct excision is first carried out, as described above.
 - The breast is accessed through an incision on the caudal portion of the periareolar pattern.
- The NAC is incised to the deep dermis, and the previously marked circumvertical pattern preliminarily stapled.
- The patient is then placed upright to visualize the resultant breast shape, and the staple line is adjusted as needed to create the desired chest contour and NAC elevation.
- After the staple line is deemed satisfactory, the patient is returned supine.
- The staple line is marked with a surgical marker, and the staples are removed.
- The intervening skin within the periareolar pattern is de-epithelialized, while the intervening skin within the vertical pattern may be de-epithelialized or removed altogether.
 - Typically, the periareolar dermis is minimally incised or not incised at all

to maintain the subdermal plexus that supplies the NAC, but the dermis of the vertical pattern may be incised to gain further access to the breast and/or facilitate flap advancement and closure.¹⁶

- The vertical pattern is closed with 4-0 Monocryl (Ethicon Inc., Somerville, NJ, USA) or equivalent interrupted deep dermal sutures followed by subcuticular closure with 3-0 Stratafix (Ethicon Inc., Somerville, NJ, USA) or equivalent absorbable barbed suture.
- The periareolar defect is closed using the periareolar purse-string technique,¹⁸ as described earlier.

TECH FIG 4 • A-C. Preoperative markings of the planned circumvertical pattern skin reduction.

PEARLS AND PITFALLS

Landmarks

- The top of the NAC is typically positioned 2 to 3 cm above the IMF by the authors. Although other techniques can be used to

calculate the ideal position of the NAC,³⁻⁸ it is ultimately the surgeon's artistic judgment that should prevail. To this end, sitting the patient up intraoperatively and tailor-tacking the periareolar or circumvertical patterns will preview the desired result and NAC position before irreversible incisions are made.

Technique

- Patients with hairy chests are advised to shave preoperatively. This will save time the day of surgery and also allow easier identification of the inferior areolar border for incision placement.
- If there is any doubt whether skin resection is required after volume reduction techniques, stage the mastopexy. Even when skin retraction is insufficient and a second-stage procedure is required, the amount of skin reduction required is usually less than originally thought, and it may be possible to reduce the amount of cutaneous scarring.¹⁶
- In cases of delayed skin envelope reduction, no additional internal dissection is required. As well, the dermal edges of the periareolar and circumvertical patterns can be safely incised at this point to facilitate tension-free closure since the NAC will have adequate secondary revascularization from its wound base.¹⁶
- A common area for persistent skin excess and fatty accumulation, particularly in obese patients, is under the arm along the lateral chest wall. The extra skin in this area can be directly excised to achieve the appropriate chest contour (**FIG 4**).
- In breasts with significant fibrofatty tissue, liposuctioning the breast tissue via various access incisions can be of mechanical advantage and help achieve a more uniform reduction in breast volume. In bilateral cases, it is helpful to use the contralateral breast incisions to liposuction the ipsilateral subareolar area (see **TECH FIG 2C**).
- When elevating the fibrous mass off the chest wall, avoid violating the pectoralis major fascia to minimize postoperative pain, bleeding, and scar tethering deep to the NAC. If possible, leave a thin layer of fat above the fascia to maintain a natural gliding plane and to avoid a “saucer” concave deformity involving the NAC.
- In patients presenting for revision gynecomastia surgery, use small liposuction cannulas to carefully control the amount of liposuction performed and avoid contour irregularities. Particularly in patients who have had only liposuction performed as the primary procedure, it is wise to perform direct excision in revision surgery to eliminate any residual breast bud and avoid further patient dissatisfaction.

Postoperative care

- It may be difficult to find compression dressings designed specifically for men. In our practice, we recommend that patients purchase a sports compression shirt that is a size smaller than the patient's normal size. If the shirt is too uncomfortable for the patient for prolonged use, the arms and bottom portion of the shirt may be trimmed so that the compression is isolated to the chest.

FIG 4 • A common area for persistent skin excess and fatty accumulation is the lateral chest wall.

POSTOPERATIVE CARE

- All incisions are covered with Dermabond; no additional external dressings are required.
- Patients are typically discharged the same day after surgery.
- Drains are usually unnecessary but, if placed, are typically removed at the first

follow-up visit.

- Routine follow-up visits are scheduled at 1 week, 6 weeks, 6 months, and yearly thereafter.
- A sports compression shirt is worn for the first 2 weeks.
- Patient may resume full activities generally 4 to 6 weeks after surgery.

OUTCOMES

- Gynecomastia surgery is generally well tolerated with patient satisfaction rates over 90%^{19–21} (**FIG 5**).
- Most patients benefit from improved emotional comfort, functional capacity, and social acceptance.^{22,23}
- Overall surgical complication rates vary from 5% to 30%, depending on the technique used.^{11,20,23–26}
- Recurrence is possible in incomplete resections or if the offending medication(s) is continued after surgery.
- Recurrence is also more likely in patients with glandular vs fibrofatty gynecomastia.²¹

FIG 5 • A–C. 1 year postoperative frontal and lateral

views of the patient in **FIG 3A–C** after combined approach with direct excision and liposuction techniques. Note the improved and more masculine chest contour after surgery, as well as the natural reduction in the size of the NACs after removal of the underlying subareolar masses. **D.** 1 year postoperative frontal view of the patient in **FIG 3D** after liposuction for volume reduction and circumvertical mastopexy for skin reduction. Note the elevated position of the NAC and improved and more masculine chest contour after surgery.

COMPLICATIONS

- Early
 - Hematoma
 - Seroma
 - Infection
 - Delayed wound healing or wound dehiscence
 - NAC necrosis
- Late
 - Adverse scarring
 - Shape change
 - Loss of nipple-areolar complex function (sensation or lactation)
 - Fat necrosis
 - “Saucer” contour deformity to the NAC

CHAPTER Juvenile Hypertrophy

Dennis Hammond and Eric Yu Kit Li

DEFINITION

- Juvenile or virginal breast hypertrophy is a rare condition characterized by atypical and pronounced breast growth during puberty in the absence of a discrete mass or nodularity.^{1,2}
- The term gigantomastia may be used to describe extreme cases.¹

ANATOMY

- At thelarche, the breast develops into glandular tissue composed of lobules and ducts and supporting stromal tissue.
- Breast development continues until the age of 18 to 20, at which point growth is complete.
- The arterial supply of the breast is derived from numerous sources, including perforators from the internal thoracic, external thoracic, thoracoacromial, and anterior and posterior branches of intercostal arteries.
 - The internal thoracic artery is the dominant source.
 - The blood supply to the nipple-areolar complex (NAC), in particular, is augmented by a rich vascular arcade that travels in a distinct fascial septum known as *Wuringer septum*³ (**FIG 1A**).
 - The arcade takes origin from the thoracoacromial, external thoracic, and intercostal arteries.
 - The septum arises approximately at the level of the 5th rib, dividing the breast into a superior two-thirds and inferior one-third, and courses from the pectoralis major fascia to the NAC (**FIG 1B,C**).
 - Preservation of the septum and its vascular arcade is key to maintaining a robust NAC during pedicle dissection in breast surgery.

- The venous drainage of the breast parallels the arterial supply.
- The lymphatic drainage of the breast is generally to the axillary and internal mammary lymph nodes.
- A variety of sensory nerves innervate the breast, including the anterior and lateral branches of the 2nd through 6th intercostal nerves and supraclavicular nerves.
 - The NAC is predominantly innervated by the lateral branch of the 4th intercostal nerve.
- The breast is enveloped by the Scarpa fascia, which forms anterior and posterior lamellae.
- Cooper ligaments are intraparenchymal fibers, which span both lamellae and confer structural support to the breast.
- The inframammary fold (IMF) is the foundation of the breast and is the point of convergence of the Scarpa fascia of the abdomen inferiorly with the anterior and posterior lamellae of the breast superiorly.⁴
 - The fat layer above the Scarpa fascia is thicker, denser, and more compact than the fat layer below it.
 - Avoidance of downward deforming pressures on the subscapal fatty layer/space, whether by an implant or parenchyma, is key to preventing “bottoming out” of the breast and undesired lowering of the IMF.

PATHOGENESIS

- The exact cause of juvenile hypertrophy is unknown.^{1,2}
- Theories include either increased end-organ sensitivity to normal levels of gonadal hormones or increased levels of gonadal hormones, although previous studies have identified normal hormone levels in juveniles diagnosed with this disease.

NATURAL HISTORY

- Juvenile hypertrophy is characterized by rapid and atypical breast growth during puberty.
- Initial growth over the first 6 months may be extreme, followed by a longer period of slower growth.
- Disease onset can be anytime during puberty, but in most cases, it is shortly after thelarche (ages 9 to 13).
- Involvement can be either unilateral, which is more common, or bilateral.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Juveniles with the suspected diagnosis should be evaluated for both signs and symptoms related to rapid breast growth.
- A detailed history should inquire about:
 - The onset and velocity of breast growth
 - The onset of puberty and ongoing pubertal development
 - Associated symptoms, including headaches; neck, shoulder, or back pain; shoulder grooving from brassiere straps; and skin irritation or intertrigo along the IMF
 - Any social, vocational, or avocational dysfunction due to the hypertrophied breasts
 - The effect of the breasts on the patient's psychological well-being and self-esteem
 - Any personal or family history of breast cancer or disorders
- A detailed physical should examine
 - The patient's height, weight, and body mass index
 - For signs related to hypertrophied breasts, including skin striae or hyperemia, peau d'orange skin, dilated subcutaneous veins, or, in severe cases, tissue necrosis involving the breast
 - For specific masses, irregularities, or deformities involving the breasts or chest wall

FIG 1 • A. Intraoperative appearance of the Wuringer septum, which is seen as a distinct white fascial layer

during pedicle dissection. **B.** The Wuringer septum is a horizontally oriented fascial condensation that spans from the pectoralis major fascia, at the level of the 5th rib, to the nipple-areolar complex. The septum contains a rich vascular arcade, which receives contributions from thoracoacromial, external thoracic, and intercostal arteries. The septum divides the breast into a superior 2/3rd and inferior 1/3rd. **C.** The IMF is the point of convergence of the Scarpa fascia of the abdomen inferiorly with the anterior and posterior lamellae of the breast superiorly. Wuringer septum is illustrated in the middle of the breast.

- Overall breast aesthetics, including the shape and size of the breasts and NACs, the degree of ptosis, and the position and symmetry of the IMFs
- Standard breast measurements to highlight asymmetries, including the sternal notch to nipple, midclavicular to nipple, nipple to midline, and nipple to IMF distances

IMAGING

- Mammography tends to be of limited value because of the density of the breast tissues in juvenile hypertrophy.
- Ultrasonography or magnetic resonance imaging may be useful in select situations, especially if masses or irregularities are identified on examination and the diagnosis is in question.
- Ultimately, diagnosis of juvenile hypertrophy is often clinical and based on history and examination.²

DIFFERENTIAL DIAGNOSIS⁵

- Physiologic breast hypertrophy (including normal growth or pregnancy-related growth)
- Benign breast tumors (eg, fibroadenoma, giant fibroadenoma, phyllodes tumor, or cysts)
- Malignant breast tumors (eg, ductal or lobular carcinoma, lymphoma, or metastases)

NONOPERATIVE MANAGEMENT

- Pharmacologic therapies, including tamoxifen, dydrogesterone, danazol, and bromocriptine, have been used as both primary treatment options or in combination with surgery, in either a neoadjuvant or adjuvant fashion.⁶
- The safety and efficacy of these therapies are not well established, however, due to the scarcity of reported cases.

SURGICAL MANAGEMENT

- Surgical treatment of juvenile hypertrophy is reduction mammoplasty.
- Surgery is ideally performed once breast size has stabilized for 6 to 12 months, but earlier intervention may be necessary if there are overriding functional, medical, or psychosocial concerns.^{2,7}
- All resected breast tissues should be sent for histopathological examination to rule out breast pathologies.
- Reduction mammoplasties are completed using the short scar periareolar inferior pedicle (SPAIR) technique.^{8,9}
- The SPAIR technique is advantageous over other techniques for numerous reasons:
 - It is versatile and can be used for breast reductions of varying size.
 - Most plastic surgeons have been trained and are comfortable using the inferior pedicle.
 - The circumvertical skin resection pattern minimizes scar burden, creates a more rounded breast shape, and improves breast projection while avoiding wound healing difficulties at the T junction or vertical segments associated with other breast reduction techniques.
 - Lessening the scar burden is a significant priority in young female patients.
 - The breast can be actively shaped with various intraoperative maneuvers to achieve the final desired contour.
 - The IMF is preserved, thus minimizing the risk of long-term “bottoming out” of the breast.

Preoperative Planning

- The patient should be seen preoperatively 1 to 3 days before surgery to achieve several objectives:
 - To review the procedure in detail and revisit goals and expectations of surgery with the patient

- To complete all perioperative paperwork, including orders, prescriptions, and instruction sheets
- To mark the patient in an unrushed, quiet, and controlled environment
- To obtain preoperative photographs of the marked patient
- Preoperative markings can be done with a variety of colored markers, each representing a specific surgical step.
 - The patient is marked in a standing position with arms at the sides.
 - A laser leveler can be used to confirm the horizontal plane across the chest.
 - The midsternal line, IMF, lateral breast contour, and breast meridian are first marked (**FIG 2A**).
 - The IMF is drawn across the chest so that it can be visualized with the breasts at rest (**FIG 2B**).
 - The periareolar pattern is outlined next:
 - The top point is the intersection of a line 2 to 4 cm above the IMF with the breast meridian (**FIG 2C**).
 - The bottom points are the top points of a rectangle, which is drawn 8 cm wide, centered on the breast meridian and arising from the IMF, with a height of 8 to 10 cm (**FIG 2D**).
 - The lateral and medial points are identified by lifting the breast up and outward and up and inward with just enough tension to create a rounded contour and transposing the breast meridian onto the breast (**FIG 2E,F**).
 - The above points are then joined together to create an elongated oval, which outlines the periareolar pattern (**FIG 2G**).
 - The superior aspect of the inferior pedicle is outlined last within the periareolar pattern:
 - The top points of the rectangle are joined with a curved line skirting the areola by 2 cm (**FIG 2H**).
 - The final design of the inferior pedicle thus comprises the area encompassed by the rectangle and the curved line.

FIG 2 • A. The midsternal line, IMF, lateral breast contour, and breast meridian are marked. **B.** The IMF is drawn across the chest. **C.** The top point is the

intersection of a line 2 to 4 cm above the IMF with the breast meridian. **D.** The bottom points are the top points of an 8- × 8- to 8- × 10-cm rectangle, centered on the breast meridian, arising from the IMF. **E,F.** The lateral and medial points are identified by manipulating the breast and transposing the breast meridian. **G.** The periareolar pattern is outlined. **H.** The top points of the rectangle are joined with a curved line skirting the areola by 2 cm.

- Preoperative photographs serve several functions:
 - They document the surgical plan electronically.
 - They can be brought to the operating room to guide intraoperative decision-making.
 - They can be compared to postoperative photographs to critically appraise surgical technique and final results.
 - They can be used to educate patients at both the pre- and postoperative settings.
- Photographs, at the minimum, should capture three standard views of the breasts including the front and each side.
 - Supplemental views, including ¾s, hands over head, and with breasts lifted by the patient, can also be taken.
 - Patients should be framed from the top of the shoulders to midway between the breast and umbilicus, with the width extending just outside the arms.

Positioning

- The SPAIR technique is performed under general anesthesia.
- The patient is positioned supine, on an operating room table that is capable of sitting up 90 degrees.
 - This will allow the patient to be placed upright intraoperatively and the breasts to be evaluated in the sitting position, which may guide intraoperative decision-making.
- The patient's head is positioned at the top of the table, supported by a foam headrest (**FIG 3A**).
- The patient's arms are placed on arm boards and secured to allow safe upright

positioning of the patient.

- Arm boards are placed at the shoulder level.
- Foam pads are placed between the arm and arm boards (**FIG 3B**).

FIG 3 • **A.** The patient's head is positioned at the top of the table, supported by a foam headrest. **B.** Foam pads are placed between the arm and arm boards. **C.** The arm is secured with a soft towel followed by a gentle circumferential wrap of gauze. **D.** The patient's knees are elevated with a pillow, and the patient's heels are supported with foam pads. **E.** A heated air-warming device is placed on the lower body.

- The arm is then secured to both with a soft towel followed by a gentle circumferential wrap of gauze, which runs from the axilla to the hand to provide a uniform layer of support (**FIG 3C**).
- The patient's knees are elevated with a pillow to relieve pressure on the back while the patient is upright, and the patient's heels are supported with foam pads (**FIG 3D**).
- A heated air-warming device is placed on the lower body (**FIG 3E**).
- The area from the top of the shoulders to midway between the inferior pole of the breast and umbilicus is prepped and draped to allow full visualization of the shoulders, chest, and breasts during surgery.

TECHNIQUES

■ Short Scar Periareolar Inferior Pedicle (SPAIR) Technique^{8,9}

Incisions

- With the breast under stretch using a tourniquet, a 40- to 52-mm areolar mark is made on the breast (**TECH FIG 1A**).
- Local anesthetic is injected into all the planned incisional areas and in the dermis of the area encompassed by the inferior pedicle.
- The areolar and periareolar incisions are made to the deep dermis, and the periareolar area de-epithelialized, except in the planned crescentric resection area above the NAC (**TECH FIG 1B**).
- The periareolar area is incised through the dermis leaving a 5-mm dermal cuff from the skin edge (**TECH FIG 1C**).
 - This dermal edge will be used ultimately for placement of the periareolar purse-string suture.

Flap Creation

- Breast flaps are then developed medially, superiorly, and laterally from the periareolar incision (**TECH FIG 2A,B**).
 - The medial and superior breast flaps are dissected thicker, aiming for 4 to 6 cm thickness (**TECH FIG 2C,D**).
 - The lateral breast flap is dissected thinner, along the plane of the outer lamina (**TECH FIG 2E**).
 - At the base of the superior breast flap dissection, the cephalic aspect of the breast septum is identified and preserved, while medially and laterally the septum is incised/released (**TECH FIG 2F**).
- The curved line skirting the areola is incised. and dissection proceeds to the pectoralis fascia to define the segment of breast tissue to be removed and free the inferior pedicle.
 - The final specimen resembles a horseshoe, with the lateral segment being larger (**TECH FIG 2G**).
 - Care is taken to avoid inadvertent undermining of the pedicle and preserve the septum.

Shaping

- Various maneuvers are now used to further shape the breast as needed.
- If the upper pole is concave, the leading edge of the superior breast flap can be advanced superiorly and fixated to the pectoralis fascia using 3-0 PDS (Ethicon Inc., Somerville, NJ, USA) or equivalent absorbable interrupted sutures to autoaugment the upper pole (**TECH FIG 3A,B**).
- If the medial pole is deficient, the medial breast flap can be imbricated upon itself on its deep surface using 3-0 PDS (Ethicon Inc., Somerville, NJ, USA) or equivalent absorbable interrupted sutures to create a more rounded contour (**TECH FIG 3C,D**).
- If either contour is excessive, the breast flaps can be further debulked as needed.
- To centralize the pedicle, the superior aspect of the inferior pedicle is sutured to the pectoralis fascia (**TECH FIG 3E,F**).

TECH FIG 1 • A. A 40- to 52-mm areolar mark is made on the breast. **B.** The areolar and periareolar incisions are made to the deep dermis, and the periareolar area de-epithelialized. **C.** The periareolar area is incised

through the dermis, leaving a 5-mm dermal cuff.

TECH FIG 2 • A,B. Breast flaps are developed from the periareolar incision. **C.** Medial breast flap. **D.** Superior breast flap. **E.** Lateral breast flap. **F.** The

cephalic aspect of the breast septum, after dissection of the superior breast flap. **G.** The horseshoe-shaped breast reduction specimen.

TECH FIG 3 • A,B. Autoaugmentation of the upper pole with sutures. **C,D.** Autoaugmentation of the medial pole with sutures. **E,F.** Suture suspension of the inferior pedicle to the pectoralis fascia.

TECH FIG 4 • A,B. Two lateral buckle points are identified, which are the starting points of the inferior pole skin plication. **C–E.** The inferior pole skin is

progressively stapled from superior to inferior, curving inferolaterally toward the IMF. **F,G**. The plication line is marked with a surgical marker. **H**. The outlined resection area is de-epithelialized, and the redundant medial and lateral wedges of tissue are removed.

Skin Plication

- The vertical pattern to manage the excessive skin enveloped is next created.
- A hemostat is applied to the superior pedicle and cephalic traction applied in line with the breast meridian to reveal two lateral buckle points, which are stapled together and represent the starting point of the inferior pole skin plication (**TECH FIG 4A,B**).
- With two hemostats applied to the dermal edge of the buckle points and upward traction (away from patient) in line with the breast meridian, the inferior pole skin is progressively stapled from superior to inferior, curving inferolaterally toward the IMF to achieve a smooth and contoured breast shape (**TECH FIG 4C-E**).
- After preliminary staple closure, the patient is placed upright to visualize the resultant breast shape and make adjustments to the staple line as needed.
- After the staple line is deemed satisfactory, the patient is returned supine, the plication line is marked with a surgical marker with hash marks to guide closure, and the staples are removed (**TECH FIG 4F,G**).
- The outlined resection area, which typically resembles a “slanted V,” is de-epithelialized, and the redundant medial and lateral wedges of tissue adjacent to the pedicle are removed en bloc (**TECH FIG 4H**).

Closure

- A drain is placed as desired, coursing around the pedicle, and brought out through the lateral breast.
- The vertical incision is closed with 4-0 Monocryl (Ethicon Inc., Somerville, NJ) or equivalent interrupted deep dermal sutures followed by subcuticular closure with 3-0 Stratafix (Ethicon Inc., Somerville, NJ) or equivalent absorbable barbed suture.
- The periareolar defect is closed last using the periareolar purse-string technique.¹⁰

- Eight evenly spaced cardinal points are marked on the areola and periareolar incision (**TECH FIG 5A**).
- A 2-0 Cytoplast (Surgiform Technologies Ltd., Columbia, SC) or equivalent PTFE suture on a straight needle is selected.
- The suture is then passed, from deep to superficial, starting on the medial dermal shelf of the periareolar incision, through the corresponding cardinal point on the dermis of the areola, inserted back into the outer dermal shelf, and then passed through the periareolar dermis to the next cardinal point.
- This weaving is continued until the suture has weaved completely around the periareolar defect, culminating in the appearance of a wagon wheel (**TECH FIG 5B**).
- The free suture ends are then tightened to cinch the periareolar incision down to match the diameter of the areola (**TECH FIG 5C**), followed by placement of 8 to 10 square knots to secure the suture.
- The knot complex is placed underneath the medial dermal shelf, and the periareolar closure is completed with 3-0 Stratafix or equivalent absorbable barbed suture (Ethicon Inc., Somerville, NJ, USA) (**TECH FIG 5D**).

TECH FIG 5 • A. Eight evenly spaced cardinal points are marked on the areola and periareolar incision. **B.**

Intraoperative appearance of the periareolar pattern after weaving of the purse-string suture. **C.** The periareolar incision is cinched down to match the size of the areola. **D.** Completed periareolar closure.

PEARLS AND PITFALLS

Landmarks

- Place the top of the periareolar pattern 4 cm above the IMF for smaller reductions and 2 cm above the IMF for larger reductions because the vertical skin resection is more significant in larger breasts, which tends to create a more pronounced lifting effect.
- Draw the rectangle below the periareolar pattern with a height of 8 cm for smaller breasts and 10 cm for larger breasts to preserve more breast skin for redraping in larger reductions.
- Push the breasts medially after all markings are completed to confirm symmetry (**FIG 4A**).
- To ensure that there is sufficient skin medially to allow tension-free redraping of the breast, the distance from the midsternal line to the medial mark of the periareolar pattern should be at least 12 cm (**FIG 4B**).

Technique

- Periareolar patterns greater than 20 cm and reductions greater than 1000 g tend to be more difficult; they require more tedious dissection and greater operator skill and culminate in more pleating and scalloping around the periareolar closure.
- The thickness of the superior and medial breast flaps can be directly controlled by adjusting the path of dissection toward the chest wall; bevel inward for lesser thickness and vice versa.
- With upward traction of the two hemostats applied to the dermal edge of the buckle points, and gentle inward pressure on the inferior pedicle along the breast meridian, the inferior breast tissues will imbricate and reveal a curvilinear path toward the IMF, which guides preliminary staple closure of the breast.
- Instead of being resected, the medial wedge of tissue adjacent to the pedicle may be de-epithelialized and preserved for more medial fullness to the reduced breast.
- If the nipple to IMF distance of the inferior pedicle is long, plication sutures can be placed on the dermis of the pedicle to

shorten the distance and improve the lower pole contour of the pedicle (**FIG 5A,B**).

- If the resultant periareolar defect after closure of the vertical segment is not circular, it can be resected again and de-epithelialized to create a circular defect that matches the areola; this will better approximate the wound edges using the periareolar purse-string technique (**FIG 5C**).

Postoperative care

- If there is any concern about the vascularity of the NAC, especially in cases in which the inferior pedicle is long, a support bra should not be worn postoperatively to avoid compression on the pedicle, and patients should be specifically educated about this to avoid unnecessary anxiety about not wearing a bra.

FIG 4 • A. The breasts are pushed medially to check that the markings are symmetrical. **B.** The minimum distance from the midsternal line to the medial periareolar pattern is 12 cm.

FIG 5 • A,B. Suture plication of the inferior pedicle to improve its contour. **C.** Planned re-resection of the periareolar pattern to create a more circular defect.

POSTOPERATIVE CARE

- All incisions are covered with Steri-Strips and Tegaderm dressings, and a support bra is worn.
- Patients are typically discharged the same day after surgery.
- Dressings remain in place for 7 to 10 days and are removed at the time of the first follow-up visit.
- Drains, if placed, are removed when their daily output is less than 30 mL.
- Routine follow-up visits are scheduled at 1 week, 6 weeks, 6 months, and yearly thereafter.
- Paper tape is applied to the healing wounds for the first 6 weeks and is changed as needed.
- A support bra is worn for the first 6 weeks.
- Patient may resume full activities, except vigorous running and weight lifting, generally 2 weeks after surgery.

OUTCOMES

- Reduction mammoplasty is generally well tolerated by adolescents from a physical and psychological perspective.⁷
- Approximately 60% of women are able to breastfeed after breast reduction.¹¹
- Approximately 2% of women lose sensation to the nipple-areolar complex after breast reduction.¹¹
- Recurrent hypertrophy is possible, especially if the reduction mammoplasty is performed during breast growth.

COMPLICATIONS

- Early
 - Hematoma
 - Seroma
 - Infection
 - Delayed wound healing or wound dehiscence
 - Nipple-areolar complex necrosis

- Late
 - Adverse scarring
 - Shape change
 - Loss of nipple-areolar complex function (sensation or lactation)
 - Fat necrosis

60 Pectus Excavatum and Pectus Carinatum

CHAPTER

Jamie C. Harris and Fizan Abdullah

DEFINITION

- Pectus excavatum is the most common chest wall deformity that involves a concave deflection of the sternum posteriorly, with a wide range of severity from slight depression to almost reaching the level of the vertebrae. This abnormality can be present at birth but more frequently becomes apparent during puberty when rapid growth occurs.
- It occurs more frequently in males than females (3:1 ratio).
- Indications for repair include symptomatic relief, improved appearance, or to alleviate psychosocial anxiety due to the defect.
- Pectus carinatum is a congenital chest wall anomaly sometimes referred to as “pigeon chest,” less common than excavatum, which is associated with a convex deformity of the sternum, leading to protrusion of the chest wall.
- Two general types are described: chondrogladiolar, which is symmetric protrusion of the body of the sternum and cartilage, and chondromanubrial, which is protrusion of the manubrium sternum with inward depression of the inferior portion. This generally presents during adolescence and has a male predominance.¹

DIFFERENTIAL DIAGNOSIS

- Pectus carinatum vs excavatum
- Poland syndrome: absence of pectoris major and minor muscles, missing ribs, and chest wall depression
- Scoliosis: abnormal curvature of the spine that can make the chest wall appear deformed

PATIENT HISTORY AND PHYSICAL FINDINGS

- As with any patient, the first approach is a thorough history. The time course of presentation is important to identify, as it can vary from infancy to adolescence.
- The progression of the deformity is important to note. For example, during puberty the deformity can rapidly become much more prominent.
- Symptoms associated with pectus excavatum (PE) are rare but can include dyspnea or exercise intolerance. However, the majority of patients will not report symptoms.
- Often, the presenting complaint is poor appearance due to the enlarging deformity at puberty.
- Clear documentation of dyspnea, exercise intolerance, or worsening dyspnea is important to facilitate insurance coverage.
- Family history regarding chest wall deformities should be obtained; there is a 25% rate of positive family history.
- Cardiopulmonary sequela has long been investigated; however, definitive results are still lacking. It has been shown that patients have normal spirometry preoperatively but can report subjective improvement in breathing postoperatively.
- On physical exam, symmetry of the chest should be examined. Often, asymmetry can occur, most frequently favoring the right side. Calipers can be used to determine the depth and width of the deformity; however, computed tomography (CT) scan has become a more standardized way to categorize defects.
- Chest wall inspection includes observing chest wall symmetry or asymmetry, as well as the type of deformity present.
- Auscultation can reveal displaced cardiac sounds. Additionally, a systolic ejection murmur can sometime be appreciated due to the proximity of the chest wall to the pulmonary artery. Mitral regurgitation can also be present.
- Examination of the rest of the body, looking for stigmata of Marfan syndrome including long digits or history of bruising. If present, a full evaluation for Marfan syndrome should be done.

IMAGING AND OTHER DIAGNOSIS STUDIES

- Computed tomography of the chest has now become important for diagnosing severity of the PE. The Haller index is calculated from the axial images using the ratio of the transverse diameter from the inner ribs to the length of the

greatest point on defect between the posterior sternum and anterior vertebrae. A ratio greater than 3.2 is considered a severe defect.²

- Plain chest radiograph, posteroanterior (PA) and lateral views, has been described to calculate the Haller index as well and in some studies has been found to be equivalent for predicting severity.³ However, most patients will generally still have CT scan for evaluation.
- Pulmonary function tests in patients with pectus excavatum have been shown to have 10% to 20% less of the expected lung volume on spirometry. Additionally, the forced expiratory volume has been shown to be less than 80% of the predicted value for patients of similar age without pectus abnormalities.⁴
- Echocardiogram for cardiac evaluation is very important in this group of patients. There is a higher prevalence of cardiac abnormalities including right ventricular compression, mitral valve prolapse and arrhythmias. An echocardiogram is important to evaluate if cardiac structure is abnormal to allow for proper operative planning if identified.⁴

SURGICAL MANAGEMENT

Preoperative Planning

Pectus Excavatum

- In general, it is preferred to time repair during the pubertal growth phase, usually from ages 10 to 15.⁵ This is because the rapid growth phase can worsen pectus and therefore cause a previously repaired defect to recur. However, for children with severe exercise intolerance, earlier repair can be considered.
- Indications for operative correction include Haller index greater than 3.2, progression of severity of disease, pulmonary function tests (PFTs) demonstrating obstructive or restrictive lung patterns, or cardiac abnormalities such as displacement, arrhythmias, or murmurs.⁶
- There are two different types of repair: open (or Ravitch procedure) and the minimally invasive procedure (Nuss). There are a few important considerations to make when deciding which approach is appropriate. In patients with severe asymmetry, the open approach is often favored. Additionally, in patients presenting with a failed Nuss procedure, the open procedure should be considered for the second repair. However, overall, the Nuss procedure tends to be the procedure of choice for consideration in lower postoperative pain as well as improved appearance from its minimally invasive nature.

- If pursuing noninvasive repair with a Nuss bar, it is crucial to determine if the patient has allergies to metal, or a family history of metal allergy. If a family history is present, subsequent skin testing for metal allergy is necessary before proceeding. If an allergy is present, a titanium bar should be used instead of the standard stainless steel.
- The bar length for the Nuss procedure should be 2.5 cm shorter than the distance from the right to left midaxillary line.⁷
- General anesthesia should be achieved prior to beginning the operation, and a secure airway must be obtained at the beginning of the case.

Pectus Carinatum

- In general, most children with pectus carinatum will not require surgery. For children that are younger and have not yet completed puberty, orthotic bracing regimens are attempted to mold the chest into the correct position. Up to 75% of patients will achieve significant or complete correction of the pectus carinatum deformity using bracing alone.⁸
- The most common reason for incomplete or failed correction is patient noncompliance with bracing regimen. Noncompliance often results from failure to wear the brace often enough or in time periods long enough to correct the deformity.
- If the defect fails to improve, surgical correction can then be pursued.

TECHNIQUES

■ **Nuss Procedure: Minimally Invasive Approach for Pectus Excavatum**

Positioning and Incision

- Patient is supine with arms extended.
- The operating surgeon is on the right and assistant surgeon on the left.
- The initial incisions should be at the transverse midaxillary line at the level of the deepest depression of the sternum, 4 cm in length on each side.

Endoscopic Bar Placement

- Once the incisions are made, carry the right-sided incision down to the

pleura, entering under direct vision.

- A 5-mm thoracoscope is inserted in two rib spaces caudal to the right-sided incision to allow for direct vision of passage of the introducer.
- Deep subcutaneous tunnels are made on both the left and right sides, staying superficial to the muscle layer.
- Next, the introducer is inserted on the right, at the level just lateral to the beginning of the indentation. The introducer is passed through the intercostal muscles.
- Under direct visualization, the introducer is passed just posterior to the sternum, using extreme caution to avoid injury to the heart (**TECH FIG 1A**).
- Upon crossing the midline, the introducer is then passed through the left-sided intercostal muscles just lateral to the edge of the depression and taken out the skin incision.
- Next, umbilical tape is tied to the introducer on the left side of the chest, pulled through the tract, and removed on the right side.
- The preformed bar is then attached to the umbilical tape, and it is then pulled through the track, with the apex of the bar angled away from the sternum (**TECH FIG 1B**).
- The bar is then rotated 180 degrees, such that the convex portion of the bar is against the sternum (**TECH FIG 1C**).
- This is secured in place using bar stabilizers on both sides. Either wire of heavy PDS suture is passed around the stabilizers and the rib to avoid bar displacement.
- For patients that have severe deformity, a second bar can be used. This is placed in the same manner, slightly inferior to the original bar.

Closure

- A 16-French red rubber catheter is placed in the tract of the camera port. A positive end expiratory pressure of 5 mm Hg is given, and a Valsalva is done by anesthesia to evacuate any residual air within the thoracic cavity. Alternatively, Valsalva without a red rubber catheter can also be used to evacuate residual air.
- The lateral incisions are then closed in layers using an absorbable suture
- The skin is closed with a running subcuticular suture
- Rarely, a chest tube is required for this procedure.

TECH FIG 1 • A. The minimally invasive approach to pectus excavatum, the Nuss procedure, inserts the bar at the level of the deepest depression. **B.** The bar is inserted with the bend away from the chest wall. **C.** The bar is then rotated 180 degrees, correcting the deformity.

■ Open Ravitch Procedure for Pectus Excavatum

Positioning and Incisions

- The patient should be in the supine position with their arms out to the side on the operating room table.
- Both the chest and abdomen should be prepped and draped into the sterile

field.

- The operating surgeon will be positioned on the patient's right, the assisting surgeon on the patient's left, and the anesthesiologist at the head of the bed.
- Two incisions can be used depending on the cosmetic outcomes. A sternal incision or transverse incision at the fourth intercostal space is used in males.
- In females, better cosmetic outcomes can be achieved using a transverse incision instead of a sternal incision. Care should be taken to make this incision within the projected inframammary crease to prevent injury to the breast bud (**TECH FIG 2**).

Exposure and Resection of the Abnormal Ribs

- Continue the incision creating skin flaps that are centered at the sternum. The skin flap should extend cephalad to the angle of Louis, the manubriosternal junction, and caudally to the xiphoid, allowing for adequate visualization of sternum and costal cartilage.
- Next, the pectoralis major muscle flaps should be elevated; passing an empty knife anterior to the costal cartilage insures the correct plane. This is continued cephalad until the highest abnormal cartilage is seen.
- Next, the rectus abdominis is mobilized off of the inferior border of the sternum.
- The perichondrium is excised anteriorly to expose the bony rib up to the sternum, exposing the cartilage at its insertion site on the sternum
- Using a Haight elevator to protect the mediastinum, the deformed cartilage is cut from the sternum using a knife. The deformed cartilage is then removed and cut at the costal cartilage junction, leaving a 5-mm margin.

TECH FIG 2 • Open repair, Ravitch procedure, is used for both pectus excavatum and carinatum. Incision is made either midline for males or inframammary in females.

TECH FIG 3 • **A.** Skin flaps are made, and the periosteum is cleared from both sides of the sternum. The deformed cartilage is cut from the sternum using a knife and removed. **B.** The sternum is then either flattened with a wedge osteotomy (for carinatum) or elevated with a transverse osteotomy (for excavatum).

- This is continued until all deformed cartilage has been resected. Then, a sternal wedge osteotomy is made just cranial to the final resected cartilage (**TECH FIG 3**).

Sternal Closure

- At the level of the osteotomy, the sternum is fractured and lifted into a flat orientation.
- Although not necessary in all cases, a sternal bar can be inserted posterior to

the sternum at this point. This is secured to the adjacent ribs for greater stabilization.

- If a bar is not used, heavy silk suture is used to close the sternal ostomy, fixing the sternum at the corrected position.
- Perichondrial sheaths are then reapproximated if necessary.

Closure

- A Hemovac drain is inserted through the inferior skin flap and placed along the sternal edge of the cut cartilage.
- The pectoralis muscle is then closed in the midline and secured to the sternum.
- The rectus muscles are then closed in the midline using an absorbable suture and reattached to the sternum.
- Layered closure of the subcutaneous tissues is done, and the skin is closed using a subcuticular stitch.

■ Open Ravitch Procedure for Pectus Carinatum

- The initial steps of the carinatum repair mirror that of the Ravitch procedure for pectus excavatum.
- The difference in technique from excavatum begins when the sternal osteotomy is made. Unlike in pectus excavatum in which a wedge osteotomy is made, a transverse linear osteotomy is made for correction of pectus carinatum at the point where the superficial deflection begins.
- The xiphoid process is detached from the sternum to allow for better sternal mobilization. The sternum is then flattened posteriorly to create a flat surface. The xiphoid process is then reattached once the sternum is in correct position.⁹
- Closure is the same as for Ravitch procedure for pectus excavatum.

PEARLS AND PITFALLS

Pectus excavatum

- Most patients with symmetric pectus excavatum are well suited for a Nuss procedure.

- Most patients who require redo surgery for pectus excavatum may benefit from a Ravitch procedure or a combined Ravitch and Nuss procedure.

Pectus carinatum

- Nonoperative treatment is the mainstay of treatment for carinatum; however, asymmetric lesions tend to require surgery more often. For symmetric deformities, bracing is first-line treatment.
- In some hands, the combination of postoperative antibiotics with sterile operative techniques has resulted in almost no wound infections in patients with pectus carinatum¹⁰

POSTOPERATIVE CARE

Pectus Excavatum

- Chest radiograph should be performed in the recovery room. This should confirm appropriate placement of the bar and also evaluate for pneumothoraces. It is not uncommon to have very small bilateral pneumothoraces that can be monitored; these usually do not require tube thoracostomy.
- Pain can be significant in the postoperative period for both procedures. Additionally, for some patients, pain can continue during the entire time the Nuss bar is in place. This pain can be managed generally with physical therapy and medications. Rarely, the bar is removed for severe pain.
- For the initial 6 weeks postoperatively, patients must refrain from any sports.
- Patients are forbidden from participating in any heavy contact sports, such as wrestling, football, and hockey for the entire duration that the Nuss bar is in place. Aerobic activities, such as running or soccer, are allowed after the initial 6 weeks.
- The Nuss bar must remain in place for at least 2 years. Timing of removal is based upon patient growth; for older patients in their rapid growth phase, removal is usually closer to 2 years. For younger patients who have not yet reached puberty, the bar can remain in place for up to 4 years.

Pectus Carinatum

- Postoperative pain is initially managed with intravenous analgesia and then transitioned to oral pain medication.
- Generally, patients are discharged within 2 to 3 days postoperatively.
- Intravenous antibiotics can be considered for 48 hours postoperatively, and

oral antibiotics are continued for another 4 days.

OUTCOMES

- No difference in length of stay between open and Nuss procedures has been demonstrated. Procedure length was slightly increased with open operation.
- The Nuss procedure is associated with higher rates of reoperation, pneumothorax, and hemothorax.¹¹
- Postoperative seroma formation is the most common complication in the open procedure. Due to this, a drain is left in the potential space within the skin flaps.
- Patient satisfaction scores have not been found to differ significantly between Nuss and open procedures, with 93.3% and 92% reported overall improved cosmetic outcomes, respectively. Symptomatic relief was also reported by both groups of patients.¹²
- Overall recurrence rates vary among studies but have been quoted between 2% and 10% in both open and Nuss procedures.¹³

COMPLICATIONS

Pectus Excavatum

- Cardiac perforation: this is an exceedingly rare intraoperative complication; however, if it does occur, it has an extremely high rate of mortality. Immediate sternotomy with cardiac repair should be done. This complication is more often associated with the Nuss procedure.
- Pneumothorax: in general, asymptomatic pneumothorax can be observed. Rarely, this may be symptomatic and require insertion of a chest tube.
- Bar dislodgement in the Nuss procedure can occur in up to 5% of patients; this can happen through the immediate or late postoperative period. If early, it can lead to immediate recurrence, and reoperation is required.
- Allergic reaction to the metal bar, ranging from rash to anaphylaxis.
- Prolonged pain, requiring bar removal in some cases.
- Recurrence has been documented after bar removal.

Pectus Carinatum

- Fortunately, complications are rare following repair of pectus carinatum.¹⁰
- Pneumothorax has been quoted at rate of 2% after repair^{10,14} but were less than 10% of total lung volume.

- Wound infection is a risk with any surgery and occurs at a very low rate.
- Recurrence/continued exercise intolerance: almost all patients report an improvement in exercise tolerance 3 to 4 months post procedure, and only 2.8% did not report an excellent result.

Section XVI: Thorax and Back

61 Myelomeningocele: Postnatal Repair

CHAPTER

Gregory G. Heuer and Jesse A. Taylor

DEFINITION

- Myelomeningocele (MMC) is a congenital malformation of the spinal cord in the family of neural tube defects and spina bifida.¹
- MMC develops from a failure of neurulation of the spinal cord during the fourth week of gestation. The exposure of the spinal cord results in dysfunction of neural tissue as a result of the malformation itself and damage to the exposed neural tissue.
- MMCs occur in roughly 1 in 1000 live births and lead to significant morbidity including bowel and bladder dysfunction, gait disturbances, and even paralysis. Importantly, lack of sensation caudal to the MMC may result in significant decubital wound issues.

ANATOMY

- The MMC results from failure of neurulation, which results in an “open book” of distinct elements that are normally closed over the spinal cord² (**FIG 1**).
- The placode, the exposed flat spinal cord tissue, is present in the center, with nerve roots running ventrally and exiting through the spine foramen. Atrophic nerve roots can often be seen exiting the placode and running to the skin and soft tissue. These are nonfunctional elements.
- The zona epitheliosa surrounds the placode and contains cerebrospinal fluid (CSF). This is part of the sac or “bubble” seen on imaging studies.

- The dura of the meninges is open and reflected and covers the fascia and muscle.
- The skin is located laterally to the lesion. Some of this tissue is extremely thin and atrophic. The quality of the skin needs to be taken into account, as it impacts surgical closure.

FIG 1 • Appearance of an MMC defect. The neural placode (*pl*) is seen at the center. This is surrounded by the zona epitheliosa (*ze*) and the skin (*sk*). The myofascial layer can often be seen through the translucent portion of the arachnoid surrounding the *ze*.

- Elements of the posterior vertebral body—the spinous process and lamina—are absent, and the spinal column is open dorsally. The open spinal column can be seen laterally as the bifida bone elements.
- In some cases, a sac is not present, and the placode is flat and in the spinal elements. This condition is known as myeloschisis and is managed in the same way as a MMC.

PATHOGENESIS

- During neurulation, normally the neural tube undergoes an ordered process of formation and closure. During this process, the neural folds meet and fuse, followed by closure of the layers around the spinal cord—including the dura, bone, muscle, and skin.¹
- MMC results from a failure of the neural tube to close at the caudal end, resulting in the exposure of the spinal cord—the placode—to the external environment.

- Most cases are idiopathic, though risk factors include genetic susceptibility and environmental risks such as toxins or medication exposure.
- Risk factors include genetic susceptibility and environmental risks such as toxins or medication exposure. In most cases, there is not an identifiable cause and is thus idiopathic.
- In some populations, the use of high-dose folic acid supplementation prior to conception can reduce the risk of neural tube defects, as folate is a known cofactor in many of the folding processes involved in neurulation.

NATURAL HISTORY

- MMC leads to irreversible loss of nerve function at the level of the exposed spinal cord.
- This loss of function occurs from³:
 - Abnormal development of the spinal cord
 - Direct damage to the exposed spinal cord from trauma and toxic injury

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with MMC are typically identified prior to birth.
- Ultrasound examination is performed for three reasons:
 - To define the MMC defect and its spinal level
 - To look at associated abnormalities of the central nervous system
 - To analyze the fetus for other structural abnormalities
- Patients with known MMC lesions are typically delivered via cesarean section.
- Newborn MMC patients are cared for in a systematic fashion (<http://www.chop.edu/clinical-pathway/myelomeningocele-myeloschisis-neonatal-clinical-pathway>).
 - General neonatal care must be the first priority, assuring that the newborn is stable and healthy and avoiding the temptation to focus solely on the MMC lesion.
 - In the presence of a MMC, the patient is generally positioned prone to avoid undue pressure on the exposed spinal elements. A sterile gauze is placed on the MMC lesion, and this is kept moist with a constant drip of sterile saline from a bag suspended above the patient.
 - The patient is placed on antibiotics (ampicillin and amoxicillin) as prophylaxis against bacterial seeding of the spinal elements.
 - Consults are obtained including the physical therapy, neurosurgery, orthopedics, plastic surgery, urology, and spina bifida team.

- An ultrasound of the head is obtained to establish a baseline of the ventricular system.
- A physical exam is performed on the infant.
 - The infant is examined for signs of hydrocephalus such as a full fontanelle, large head circumference, or splayed sutures.
 - In most instances, newborn MMC patients do not show clinical signs of hydrocephalus until after the MMC closure is performed.
 - The anatomy of the MMC defect is similar (see **FIG 1**) even if the overall appearance of the lesion may be grossly variable (**FIG 2**).
 - The size of the MMC lesion is noted as well as the quality of the skin. These factors are important to anticipate the need for specialized closure techniques such as rotational flaps, allograft patches, or skin grafts.
 - A neurologic exam is performed to assess the clinical level of function. The clinical exam is very difficult to interrupt in a newborn and should be done by a trained clinician and followed over time for any changes. Movement secondary to direct stimulation that is not clinically significant can be present below the level of the lesion and should not be confused with volitional movement.⁴
 - The infant should be examined for orthopedic deformities, such as talipes or hip contractures. These are important to note prior to the MMC closure as they may affect patient positioning both before and after surgery.
- Surgical closure of the MMC is typically performed within the first 48 hours after birth.
 - However, this can be delayed if the patient is not clinically stable as long as the positioning, wound care, and prophylactic antibiotics are administered. The risks of delaying surgery must be carefully weighed against the risks of infection and further neurological deterioration. If the surgery is delayed for weeks to months, the granulation tissue that develops can increase the technical difficulty of the closure.
- MMC closure is performed in a stepwise fashion to close the layers over the spinal cord that should be present.

SURGICAL MANAGEMENT

- The overall goal of the surgical closure is to obtain a multilayer closure of all three layers of the back—dura, muscle, skin—that is watertight.

Positioning

- The infant is placed prone with the abdomen suspended to promote venous return and reduce bleeding during surgery (**FIG 3**).
- The back is widely prepped on the table with Betadine. The back must be prepped in a wide fashion to allow for skin rotational procedures.

FIG 2 • Various MMC lesions. Note the variability in the size and appearance of the lesions.

FIG 3 • Intraoperative positioning of an MMC patient.

TECHNIQUES

- **Release of the Placode**

- The tissue just lateral to the placode is sharply incised, releasing the placode to float ventrally into the spinal column (**TECH FIG 1A**).
- It is often necessary to make this incision further from the placode and the residual tissue should be dissected from the placode.
- The placode can be rolled back into a tubular structure by placing sutures in the pial layer. This is often accomplished with 6-0 Prolene interrupted sutures (**TECH FIG 1B**).

TECH FIG 1 • A. Dissection of the placode from the surrounding tissue. **B.** The released placode is brought into a tubular shape with fine sutures.

■ Skin Release and Mobilization

- The skin is then released from the underlying fascia and muscle (**TECH FIG 2**).
- The skin is undermined widely, resulting in greater exposure of the underlying fascia and freeing up soft tissues that can be more easily rotated over the fascia during the skin closure.
- Care needs to be taken to stay in the proper plane and avoid tearing the skin and soft tissues during this undermining process.
- The edges of the skin are then trimmed back to the tissue that will support dermal and skin sutures.

TECH FIG 2 • The skin is extensively undermined.

■ Dura, Myofascial, and Skin Closure

- The next step is closure of the lateral tissue over the placode. The goal of the closure is a watertight closure over the placode.
- The skin is held with a retractor, exposing the lateral dura and fascia.
- An incision is made in the lateral tissue. This tissue is normally the dura that

is present over the top of the muscle and fascia.

- This is carefully mobilized over the underlying tissue and rotated over the placode (**TECH FIG 3A**).
- The dura may be thin or absent in the sacral portion of the MMC.
- The next layer is the myofascial layer (**TECH FIG 3B**).
 - An incision is made in the fascial layer. This needs to be several centimeters away from the opening to allow it to be rotated over the dural closure without tension. Mobilization of the layer can be assisted by releasing this layer from the opening spina bifida elements.
 - This layer is rotated to the midline and closed (**TECH FIG 3C**).
- After closure of the myofascial flaps, the skin is further undermined. Additionally, extension of the superior and inferior skin edges can increase the mobilization of the skin flap.
- The skin flaps are then rotated to the midline and closed in two layers (**TECH FIG 3D**).

Additional Maneuvers

- If the skin cannot be mobilized, additional maneuvers are sometimes needed.
- This can include placing an AlloDerm patch (LifeCell, Branchburg, NJ) (**TECH FIG 4**), relaxing incisions in the posterior axillary line, or Z-plasty extensions.

TECH FIG 3 • **A.** The dural flaps are rotated over the placode and closed in the midline. **B.** Exposure of the lateral myofascia. **C.** Rotation and closure of the myofascial flaps. **D.** Appearance of the skin after closure.

TECH FIG 4 • Appearance of a large MMC preoperatively (**A**), which resulted in a skin wound (**B**) that required an AlloDerm patch (**C**).

PEARLS AND PITFALLS

Closure

- A multilayer watertight closure is essential to prevent wound breakdown and protect the placode from further damage or infection.
- If fluid collections form that are consistent with pseudomeningoceles, this needs to be treated, normally with CSF diversion.
- It is important to be aware of the vascular supply to skin flaps to prevent necrosis of the skin when performing Z-plasty or relaxing incisions.

Intraoperative care

- The patient needs to be positioned to take pressure off the abdomen and other pressure points; this will promote venous return, reduce bleeding, and prevent pressure sores.
- The patient should be prepped and draped widely to allow multiple options for skin closure.

POSTOPERATIVE CARE

- The patient is cared for in the neonatal ICU. Close observation for bladder dysfunction, pressure points, and orthopedic issues is paramount.
- Special attention should be paid to the examination of the wound. Wound care is very important as the wound is in the lumbosacral area and is prone to

contamination with stool or urine. A drape separating the anal region from the MMC closure should be placed to divert stool, but local wound care must be maximal to prevent infection.

- The child needs to be monitored for the development of hydrocephalus. In patients with a full fontanelle, enlarging pseudomeningoceles, or other clinical signs of hydrocephalus, they should be treated with CSF diversion, either with a ventriculoperitoneal shunt or an external ventricular catheter.

62 Myelomeningocele, Prenatal (Fetal) Repair

CHAPTER

Gregory G. Heuer and Scott N. Adzick

DEFINITION

- Myelomeningocele (MMC) is a congenital malformation of the spinal cord in the family of neural tube defects and spina bifida as described in the previous chapter (Myelomeningocele, Postnatal Closure).
- Prenatal surgery was first attempted in the 1990s. A randomized controlled trial, the Management of Myelomeningocele Study (MOMS), demonstrated that closure during the prenatal period could be performed relatively safely and can result in significant benefit to the child.¹

ANATOMY

- The MMC results from failure of neurulation resulting in an “open book” of distinct elements that are normally closed over the spinal cord (**FIG 1**) as described in the Myelomeningocele, Postnatal Closure chapter.

PATHOGENESIS

- During neurulation, normally the neural tube undergoes an ordered process of formation and closure as described in the Myelomeningocele, Postnatal Closure chapter.

NATURAL HISTORY

- MMC leads to irreversible loss of nerve function at the level of the exposed spinal cord as described in the previous chapter (Myelomeningocele, Postnatal Closure).
- In addition, a fetus with MMC will progressively develop two associated conditions as the result of the continued cerebrospinal fluid (CSF) leak, a Chiari malformation with hindbrain herniation and hydrocephalus.²

FIG 1 • Appearance of an exposed MMC defect during a fetal repair. The neural placode (*pl*) is seen at the center. This is surrounded by the zona epitheliosa (*ze*) and the skin (*sk*). The myofascial layer (*mf*) covered by dura can be seen through the translucent arachnoid.

PRENATAL EVALUATION

- Expectant mothers receive extensive prenatal testing to determine if they are candidates for prenatal surgery. The inclusion and exclusion criteria in the MOMS trial are still used by most fetal therapy centers (Table 1).³
- Ultrasound (US) examination is performed for three reasons: to define the MMC defect and its spinal level, look at associated CNS abnormalities, and evaluate the fetus for other structural abnormalities.
- With regard to the MMC defect and CNS-associated conditions, US is used specifically:
 - To define the level of bone and skin opening
 - To analyze the posterior fossa, specifically to look for the presence of hindbrain herniation (must be present as it confirms an open neural tube defect)
 - To determine the size of the lateral ventricles and degree of ventriculomegaly
 - To look for any associated abnormalities such as a spinal cord syrinx, a split cord malformation, or a significant kyphosis that may affect the eligibility of the patient for fetal MMC repair.
- Patients also receive a fetal magnetic resonance imaging (MRI) scan. These scans provide a more detailed anatomic evaluation of the MMC defect and associated abnormalities, particularly the presence of hindbrain herniation.

- In addition to imaging, the fetus undergoes an analysis for genetic or chromosomal abnormalities. Also, amniotic fluid analysis is performed to confirm an open neural tube defect.
- A detailed medical history for the mother is obtained, specifically looking for significant maternal health issues and risk factors associated with premature delivery.

SURGICAL MANAGEMENT

- The overall goal of the surgical repair is to obtain a multilayer closure that is watertight. To provide the greatest possible benefit to the fetus, the closure needs to protect the neural structures from direct trauma, prevent the leakage of CSF, and prevent the exposure of the neural structures to amniotic fluid. Additionally, the closure needs to be done in a manner that is safe for the fetus and the mother, as extreme premature birth can erase all potential gains of the surgical procedure. There are some modifications of the general technique outlined below, but the principles above should not be compromised.

Preoperative Planning³

- A preoperative US is obtained to confirm the location of the fetus and the placenta.

Table 1 MOMS Trial Inclusion and Exclusion Criteria

Inclusion	Singleton pregnancy
	Lesion level T1-S1
	Evidence of hindbrain herniation
	Gestational age of 19.0–25.9 weeks
	Normal karyotype
	U.S. residency
	Maternal age of 18 years or older
Exclusion	Fetal anomaly unrelated to myelomeningocele
	Severe kyphosis greater than or equal to 30 degrees
	Multiple gestation
	Previous spontaneous preterm birth less than 37 weeks
	Short cervix less than 20 mm
	Placental abruption or abnormal placentation (placenta previa)

	Obesity defined as BMI > 35
	Maternal medical condition that would place an additional risk to maternal health/surgical risk or the pregnancy (insulin-dependent diabetes, poorly controlled hypertension)
	Documented history of incompetent cervix or planned/current cerclage
	Maternal-fetal Rh isoimmunization, Kell sensitization, or a history of neonatal alloimmune thrombocytopenia
	Maternal HIV, hepatitis B or hepatitis C positivity
	Uterine anomaly such as multiple fibroids or müllerian duct abnormality; previous hysterotomy in the active segment of the uterus
	Patient does not have a support person
	Inability to comply with the travel and follow-up requirements
	Patient does not meet other psychosocial criteria to handle the implications of the trial
	Participation in another study that influences maternal and fetal morbidity and mortality or participation in this trial in a previous pregnancy

- The mothers receive an epidural catheter for delivery for intraoperative and postoperative pain control.
- Antibiotics and indomethacin are given.

Positioning and Anesthetic Concerns³

- The mother is placed supine on the operating room table with a bump placed under the right side to avoid inferior vena cava compression by the gravid uterus and compromise of venous return.
- The surgery is performed under deep general anesthesia, with the goal to achieve maximum uterine relaxation. In addition to maternal anesthetic, the fetus receives a direct dose of intramuscular anesthesia (vecuronium and fentanyl).
- The cardiac function of the fetus is continually monitored by fetal echocardiography. If a decrease in cardiac function is seen, the anesthetic to the mother is adjusted or the fetus is examined for signs of umbilical cord or

placental compression.⁴

- An arterial line is placed in the mother.

Approach

- The uterus is approached via a low transverse maternal laparotomy. Of note, the uterus is opened in the upper muscular portion and not the lower segment used for typical cesarean sections (**TECH FIG 1A**).
- The site of the placenta is mapped out on the surface of the uterus. If the placenta is anterior, the uterus is rotated out of the abdomen to gain access to the fundus and posterior uterine wall. The goal is to open the uterus at least 6 cm away from the placental edge. In addition to the placenta, the location of the fetus is noted so that the hysterotomy is made directly over the MMC defect to minimize the need for manipulation of the fetus. In some cases, the fetus is moved prior to opening the uterus to aid in this exposure.
- The uterus is opened under continuous sonographic visualization.
 - Two monofilament traction sutures are placed through the full thickness of the uterus.
 - A Bovie cautery is then used between the sutures and the uterus opened.
 - An atraumatic clamp is placed through this opening to compress the uterine tissue and to facilitate the firing of a specialized uterine stapling device that is only partially inserted. This device places a row of absorbable polyglycolic acid staples across the uterine wall and fetal membranes. This device cuts the uterine wall at the same time it places the staples, holding the layers together in a normal anatomic position and occluding crossing blood vessels. This is then repeated in the opposite direction to create the 6-cm hysterotomy.
 - An infusion of body temperature lactated Ringers with a level I infusion device is used to maintain the uterine volume and keep the fetus warm and buoyant.
 - The fetus is then held in the hysterotomy incision so that the back and MMC defect are in the opening.
- After the MMC repair the uterus and then the maternal laparotomy are closed in a layered fashion.
 - Full-thickness stay suture is placed first, followed by a running full-thickness layer that incorporates the absorbable staples. During this closure the uterus is filled with the lactated Ringers solution to reconstitute the amniotic fluid volume, and intra-amniotic antibiotics are added.
 - The running layer suture is tied followed by tying of the individual stay

sutures.

- The uterine closure is then covered with an omental patch to help seal it and provide blood supply.
- The laparotomy wound and skin are then closed.

TECHNIQUES

- Fetal MMC repair is performed in the same manner as postnatal repair. There are three important differences to the prenatal repair compared to the postnatal repair.⁵
 - First, one advantage of fetal MMC closure is the chance to maintain spinal function, and therefore, even greater care is needed in the fetal patient to minimize any trauma to the placode and neural tissue.
 - Second, the fetal tissue is more delicate than in a newborn, and therefore it may tear with even minor manipulation.
 - Lastly, maneuvers, such as pulling the skin tightly, that may be tolerated in a newborn may lead to cardiac depression in the fetus and are therefore avoided.

■ Release of the Placode

- The tissue just lateral to the placode is sharply incised, releasing the placode to float ventrally into the spinal column (**TECH FIG 1B**).

TECH FIG 1 • The laparotomy incision is shown in **A**. The incision in the uterus is performed in the upper segment. **B**. The exposed MMC defect. The fetus is positioned to allow access to the MMC defect and monitor the fetal cardiac function. **C**. The exposed MMC defect is then repaired.

- It is often necessary to make this incision further from the placode than desired to avoid damaging the spinal cord or exiting nerve roots. In these cases, the residual tissue should be dissected from the placode to reduce the risk of subsequent inclusion cyst formation.
-

■ Skin Release and Mobilization

- The skin is then released from the underlying fascia and muscle.
 - The skin is undermined using scissors in an elliptical fashion for several centimeters.
 - Undermining of the skin allows the skin to be mobilized, resulting in greater exposure of the underlying fascia and skin that can be more easily rotated over the fascia during the skin closure.
 - Care needs to be taken to stay in the proper plane and avoid tearing the skin during this undermining process.
-

■ Dura and Myofascial Closure

- The next step is closure of the lateral tissue over the placode.
- The goal of the closure is a watertight closure over the placode.
 - The skin is held with a retractor, exposing the lateral dura and fascia. The skin opening can be extended superiorly and inferiorly to aid in the exposure of the fascia.
 - An incision is made in the lateral tissue and this tissue is then rotated over the released placode. Some authors close only the dural layer, but we prefer a thick myofascial flap with the dural layer on the mesial surface to ensure watertight closure and direct contact between the delicate dural layer and the neural placode.
 - The myofascial flaps are then closed with a running suture such as a 4-0 polydioxanone (PDS). When this thick layer is closed in the midline, care is taken to approximate the dural surfaces and to protect the placode. This protection can be assisted with placement of a freer retractor over the placode during the suturing (**TECH FIG 1C**).

Skin Closure

- After closure of the myofascial flaps, the skin is further undermined.
- The skin flaps are then rotated to the midline; an assessment is then made if

flaps can be rotated to the midline without tearing the tissue significantly or leading to tension-related cardiac depression.

- A running monofilament, such as 4-0 PDS, is placed. The suture should be placed loosely; once the suture has been placed across the opening, the suture is pulled tight after each stitch in a stepwise fashion until the skin edges meet. This “lacing” technique allows the tension to be spread across the incision and reduces tearing. Additionally, to reduce the chance for tearing the suture through the skin, the suture should be placed away from the skin edge and in the thicker portion of the skin flaps.
- If the skin cannot be closed, a graft is then sized to the opening. This graft is normally constructed with AlloDerm (LifeCell, Branchburg, NJ) and is elliptical in shape. It is sutured with two running monofilament sutures.
- Other groups have described the use of relaxing incisions in the flank to aid in mobilization. However, these are generally not used because they are at risk to fail from devascularization after skin mobilization.

PEARLS AND PITFALLS

Selection	■ A detailed study of the mother and fetus is necessary for proper patient selection, confirming the presence of an open neural tube defect and no other associated fetal or maternal abnormalities that will prevent a good outcome.
Closure	■ A multilayer watertight closure is essential for maximal benefit to the fetus. ■ The goal of the surgery is to release the neural tissue and then rotate and close the layers over the placode, consisting of the dura, muscle, and skin.
Intraoperative Care	■ A dedicated fetal team is essential for a good outcome. This team should include fetal surgery, experienced anesthesia, obstetrics, and fetal cardiology.
Outcome	■ Fetal MMC repair can result in significant benefits for motor function, reversal of hindbrain herniation, and reduction in hydrocephalus.

POSTOPERATIVE CARE

- Postoperative care is focused on maintaining the pregnancy.
- During the operative procedure, the mother is given a bolus of magnesium sulfate and started on an infusion. This reduces uterine contractions and the risk for premature delivery. This infusion is continued for the first 18 to 24 hours.
- The mother is started on oral nifedipine after the magnesium sulfate infusion.
- The mother is given indomethacin prior to surgery, and this is continued for 48 hours postoperatively.
- The mother is observed as an inpatient for an average of 4 days and then is discharged to modified bed rest. The mother is followed closely for signs of premature labor or amniotic fluid leakage.
- Delivery is performed via an elective cesarean section prior to the development of labor and contractions, as this could lead to uterine rupture. The goal is to deliver at 37 weeks, but often the delivery is performed earlier than this time.

CHAPTER Sacrococcygeal Teratoma

Nicholas J. Ahn and William H. Peranteau

DEFINITION

- Usually benign extragonadal germ cell tumor that develops prenatally, involving the coccyx with various degrees of pelvic and intra-abdominal involvement.
- It is the most common congenital neoplasm found in fetuses and neonates.
- Between 11% and 35% of the tumors may contain malignant elements such as yolk sac tumor or embryonal carcinoma.¹
- Large or solid tumors may lead to poor clinical outcomes due to high-output cardiac failure, hydrops fetalis, tumor rupture, or internal hemorrhage.²
- Surgical resection is the mainstay of treatment but has associated morbidities such as problems with micturition, defecation, or cosmetic dissatisfaction up to 40% to 50%.³ Large tumors with significant pelvic/intra-abdominal involvement have the most significant risk for urologic and anorectal complications.⁴

ANATOMY

- All sacrococcygeal teratomas (SCTs) involve the coccyx but are classified into four categories according to the location and extent of the tumor—the Altman Classification Scheme.⁵
 - Type I: primarily external with a small presacral component
 - Type II: external with intrapelvic extension
 - Type III: primarily pelvic and intra-abdominal with external component
 - Type IV: completely intrapelvic with no external component

PATHOGENESIS

- SCTs are thought to originate from the primitive knot (also known as Hensen node), where the three germ cell layers start to form.
- SCTs may be cystic, solid, or a mix of both. Solid tumors tend to be more vascular and are associated with an increased risk of high-output cardiac failure, hydrops fetalis, tumor rupture, hemorrhage, and fetal demise.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The majority of the lesions are now diagnosed by the time of birth as early as 18 to 19 weeks of gestation due to advancement in antenatal imaging.
- Type I to III lesions that are not diagnosed prenatally are identified at birth by an obvious protruding mass originating from the sacral region.
- A rectal exam must be performed to assess the degree of intrapelvic extension of the tumor, especially for tumors that were diagnosed postnatally.
- Rarely, some type IV lesions can go undiagnosed until the child is up to 4 years of age and present with compressive symptoms of the bladder or rectum, such as urinary retention, obstruction, or constipation.

IMAGING

- Most SCTs are diagnosed prenatally at the time of approximately 20-week gestation fetal anatomy ultrasound. If diagnosed, the mother and fetuses should be referred to a high-volume multidisciplinary fetal diagnosis and treatment center where a high-resolution fetal ultrasound will be performed to assess the anatomical extension of the tumor and the characteristics of the mass (solid, cystic, vascularity) (**FIG 1A**).
- Ultrafast fetal MRI is used as an adjunct to ultrasonography to better assess the SCT, including the pelvic or abdominal extension of the tumor and its involvement with surrounding structures such as the colon, urinary tract, vagina, hip, and especially the spine (**FIG 1B**).
- After birth, hemodynamically stable infants may undergo a CT scan or MRI to assess the extent of the tumor for preoperative planning (**FIG 2**).

DIFFERENTIAL DIAGNOSIS

- Meningocele
- Lymphangioma
- Enteric duplication cyst
- Dermoid cyst
- Retrorectal hamartoma

- Meconium pseudocyst
- Tail remnant
- Lipoma

FIG 1 • Prenatal SCT imaging. **A.** High-resolution fetal ultrasound demonstrating a predominantly cystic type I SCT with blood supply originating from the hypogastric vessel. **B.** Ultrafast fetal MRI demonstrating a large type I SCT that has solid and cystic components.

FIG 2 • Postnatal SCT imaging. Postnatal CT scan demonstrating a predominantly type II SCT.

SURGICAL MANAGEMENT

Preoperative Planning

- Fetuses with external tumors that are larger than 5 cm, predominantly solid, or have a significant vascular supply should be delivered by cesarean delivery to decrease the risk of catastrophic bleeding or tumor rupture.
- If the patient is stable, the tumor can be resected within the first week of life.
- CBC, type and screen, and cross-match must be performed in anticipation of surgery.
- Alpha-fetoprotein (AFP) and β -HCG levels should be obtained prior to surgery.
- CT scan or MRI of the abdomen and pelvis with contrast should be performed as discussed above in stable patients.

Positioning

- Most type I and type II lesions can be resected with the patient in prone jackknife position and completely resected from the posterior approach (**FIG 3**).

FIG 3 • Positioning. Prone position of newborn with large type I SCT.

- Lesions with significant intra-abdominal components often require an anterior (laparotomy) as well as posterior approach for complete resection and thus should be positioned supine for the anterior approach initially.
- Towel rolls or gel pads should be used to support the patient's shoulder and

pelvis from underneath when in the prone position.

- If uncertain regarding possible laparotomy, the patient should be sterilely prepped from the chest to the toes to allow for free intraoperative repositioning without repreparation and draping.

Approach

- Most type I and II lesions can be completely resected from the posterior approach.
- Lesions with large intra-abdominal components (some type III and type IV) require a combined anterior approach via a laparotomy and a posterior approach.

TECHNIQUES

■ Posterior Approach (TECH FIG 1)

- Landmarks: gluteal crease, sacrococcygeal junction, anal orifice
- A Foley catheter is placed prior to placing the patient in the prone jackknife position.
- The incision is made over the external component of the tumor in an orientation that allows for the development of large skin flaps. This often involves a transverse incision in an inverted V shape that starts at the sacrococcygeal junction.

TECH FIG 1 • Posterior approach for postnatal SCT resection. **A.** Most type I and II SCTs can be approached from the posterior approach. Care must be taken to identify the anus/rectum to avoid injuring it. The coccyx is identified and resected with the specimen. The surgeon must also try to save the attenuated muscle fibers to reconstruct the pelvic floor following tumor resection. **B.** Resected specimen. Ideally the tumor and coccyx are resected as a single specimen. Often thin, extra skin is resected with the tumor specimen as there is frequently redundant skin available for appropriate skin closure. **C.** Skin closure following SCT resection.

- The incision is carried down to the tumor capsule, which, in many cases, is very superficial.
- Being cognizant to stay on the tumor capsule to preserve attenuated muscle fibers that will later be used to reconstruct the pelvic floor, the tumor is circumferentially dissected out as skin/muscle flaps are raised.
- Identify and always be cognizant of the position of the anus and rectum, which are often displaced and closely opposed by the SCT. Placement of a Hegar dilator or large red rubber catheter in the anal opening helps the surgeon identify and avoid injury to the anus/rectum.
 - For tumors with a large intrapelvic component, similar attention should be paid to the ureters.
- Dissection of the tumor along its posterior superior border will lead the surgeon to the coccyx, which must be identified and resected.
 - The sacrococcygeal junction is identified and circumferentially dissected out.
 - Care is taken to stay on the anterior surface of the sacrococcygeal junction during dissection to avoid injury to the vascular supply to the tumor that usually originates from the middle sacral artery or branches from the hypogastric.
 - With an instrument on the anterior surface of the coccyx to protect underlying vessels, the sacrococcygeal junction is transected with a Bovie.

- Ligate the vascular supply to the tumor after the coccyx is transected at the sacrococcygeal joint.
 - The tumor and coccyx are ideally resected as a single specimen (**TECH FIG 1B**).
 - The muscles of the pelvic floor and anorectal sphincter are reconstructed.
 - Excess skin is removed to allow for the best appearance.
 - The skin is often closed in a “Mercedes” sign but can be closed in a vertical incision (often following complete resection after an initial debulking, see below) if more cosmetically appropriate (**TECH FIG 1C**).
 - If large skin flaps are raised, the skin is closed over a small drain.
-

■ Anterior Approach

- Tumors with large intra-abdominal/intrapelvic components often require a laparotomy via an anterior approach in combination with the above posterior approach.
 - The anterior approach is done initially with the goal of identifying and controlling the vascular supply to the tumor prior to significant dissection of the tumor.
 - Large intra-abdominal/intrapelvic tumors may be closely associated with the colon, intestinal mesentery, and the ureters all of which should be identified and preserved.
 - The laparotomy is performed via a transverse incision between the umbilicus and pubic symphysis or, in cases with a very large intra-abdominal component, may be approached via a midline incision.
 - After controlling the vascular supply to the tumor and dissecting out the intra-abdominal component of the tumor, the patient is flipped to the prone position and the remainder of the tumor and coccyx resected.
-

■ Special Considerations—Debulking (**TECH FIG 2**)

- Large, predominantly solid lesions often have increased tumor vascularity and may be associated with high-output cardiac failure prenatally or immediately after birth. Fetuses with these lesions require close prenatal follow-up with assessment by high-resolution ultrasound often twice a week to monitor combined cardiac output and for signs of hydrops fetalis.

- If the SCT has a significant solid external component and there are signs of hydrops or early heart failure, the fetuses may be a candidate for debulking of the external component of the SCT. Depending on the gestational age of the fetus, this may occur as a cesarean delivery with immediate debulking after birth or open fetal surgery.^{2,6}
- The techniques of open fetal surgery are beyond the scope of this chapter.
- Surgical debulking includes the following:
 - A posterior approach to the tumor
 - The anus is identified and a Hegar dilator or red rubber catheter placed to assess the tract of the rectum.
 - The skin at the base of the external component of the SCT is scored with a Bovie.
 - A tourniquet consisting of an umbilical tie, and a cut large red rubber catheter is placed at the base of the SCT where the skin had been scored.
 - The tourniquet is tightened, and a harmonic scalpel is used to transect the tumor above the level of (distal to) the tourniquet.
 - The tourniquet is slowly released, and hemostasis is obtained by oversewing bleeding vessels with a 5-0 Prolene.
 - The skin is reapproximated and sutured over the cut edge of the tumor.
 - The infant is then resuscitated and cared for in the neonatal intensive care unit.
- All patients undergoing surgical debulking will require a second operation to complete the resection of the tumor, including the coccyx, once the infant is stable and well recovered (usually greater than 6 weeks after debulking).

TECH FIG 2 • SCT debulking. Large type I SCTs that threaten hemodynamic stability may require debulking prior to or immediately after birth. Some of the main instruments required for debulking (**A**). The skin of the tumor is scored with a Bovie near the base of the SCT (**B,C**). A tourniquet constructed from an umbilical tie, and a cut large red rubber catheter is placed around the base where the skin was scored (**D**). A harmonic scalpel is used to transect the tumor above the

tourniquet **(E,F)**. The tourniquet is released and bleeding vessels oversewn. Note, unlike formal resection of an SCT, debulking does not remove the coccyx or intrapelvic/intra-abdominal tumor components **(G)**. These components will be resected after recovery and stabilization from debulking.

PEARLS AND PITFALLS

Positioning and prep

- If uncertain of need for laparotomy, prep the patient from lower chest to toes to allow for repositioning during the case without the need for new prep and drapes.

Technique

- A Hegar dilator can be used to identify the rectum and avoid damage.

Complete resection

- The coccyx must be resected to lower the risk of recurrence.

POSTOPERATIVE CARE

■ Immediate postoperative care

- The patient should be positioned to avoid pressure on the wound as much as possible.
- The wound should be monitored for bleeding, dehiscence, or infection.
- If the tumor had a significant intrapelvic extension, urinary retention may occur, requiring a Foley catheter or intermittent catheterization.

■ Follow-up

- Final pathology should be followed up to rule out malignancy.
 - Benign lesions may be managed with surgical resection and observation alone.
 - If malignant elements are noted on histology, a consultation with oncology may be needed.
- All patients should be followed long term with rectal examinations and AFP levels every 3 to 6 months until the age of 3.

- The AFP level should return to normal by 9 months.
- If still elevated after 9 months or a mass is palpated on rectal exam, an MRI or CT scan must be performed in suspicion of a recurrence.

■ Recurrence

- Tumor spillage, incomplete resection, and malignant or immature histology are risk factors for recurrence.
- If recurrence is noted, a full metastatic workup including a CT chest, abdomen, pelvis, and laboratory studies are required.
- Management of recurrence requires re-excision with or without chemotherapy.

OUTCOMES

- The survival rate is greater than 90% if SCT is diagnosed on routine prenatal ultrasound.
- If the indication for the ultrasound examination was due to another complication of pregnancy, the mortality rate increases to 60%.
- If hydrops or placentomegaly is present, the mortality almost reaches 100%^{2,7} if no intervention performed.
- Recurrence after resection occurs in about 10% to 15% of all patients with SCT, as early as 1 month to as far out as 59 months post-op (median 10–16 months).
- Survival rate is decreased with recurrence: 90% without recurrence and 65% with recurrence.

COMPLICATIONS

- Prevalence of anorectal morbidities including severe constipation and fecal incontinence ranges from 6% to 60% of the patients.
- Urologic bladder, vesicoureteral reflux, and urinary incontinence can manifest in 5% to 45% of the patients.
- Large intrapelvic extension of the tumor is associated with these morbidities.⁴

Section XVII: Abdomen

64

CHAPTER Prune Belly

Jamie C. Harris and Fizan Abdullah

DEFINITION^{1,2}

- Prune belly is an extremely rare disease, occurring in 1/35 000 live births. The majority of patients are male (**FIG 1**).
- It is characterized by three components: abdominal wall flaccidity, bilateral undescended testes, and urologic anomalies.
 - Abdominal wall laxity is associated with increased rates of respiratory infections, due to a poor cough mechanism, as well as increased incidence of lordosis.
 - Urinary tract anomalies lead to increased rates of infectious complications as well as ureteral obstruction; 81% of patients have megaureter.
 - Urinary tract abnormalities can include renal dysplasia and ureteral enlargement.
 - Additionally, both testes are intra-abdominal in the majority of patients.
- Overall outcome of the children is variable, with some not surviving past the neonatal period due to complications to some with minimal disease complications.

DIFFERENTIAL DIAGNOSIS

- Prune bellylike variant: abdominal flaccidity. However, unlike in prune belly, the rectus muscles are not involved.

Patient History and Physical Findings³

- Prenatal history is often unremarkable. However, oligohydramnios may be present.
- Physical examination

- A wrinkled abdomen with more laxity noted in the medial and inferior regions. This is a distinctive feature of prune belly. There will be redundant skin over the abdomen.

FIG 1 • This demonstrates the laxity in the abdominal wall of prune belly.

- As the children age, the abdomen will look more protuberant and less wrinkled.
- If portions of the urinary system are massively dilated, these can sometimes be palpated on abdominal exam.⁴
- Scrotal exam will reveal bilateral absence of testes in the majority of cases.
- Cardiac anomalies can be associated with prune belly; a cardiopulmonary exam should be included to listen for murmurs.
- Close monitoring of urine output is important to identify any obstructive uropathy that may be present. If present, nephrostomy tubes can be considered for urinary decompression.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Prenatal ultrasound
 - Hydroureteronephrosis, bladder distension, oligohydramnios, and cryptorchidism can be seen on prenatal ultrasound.⁵
- Postnatal urinary tract evaluation
 - Serum creatinine measurements

- This will identify any worsening renal function.
- Baseline measurements should be obtained at birth and trended to determine changes in function, creatinine greater than 0.7 mg/dL has a higher rate of developing renal failure.⁶
- Kidney Ureter Bladder radiograph (KUB):
 - Evaluation of the bowel for dilatation can be done using a KUB. Bowel will extend over the lateral edge of the abdominal wall, which is diagnostic of prune belly.
 - Due to the lack of abdominal wall structure, intestinal malrotation can occur due to poor fixation to the abdominal wall.⁴
- Renal and bladder ultrasound⁴:
 - An ultrasound will demonstrate atresia or absent kidney, hydronephrosis, megaureter, tortuous ureters, or megabladder.⁷
- Voiding cystourethrogram (VCUG):
 - This is used for evaluation of the urethra. It can evaluate for vesicoureteral reflux. If identified, prophylactic antibiotics are indicated.
- Evaluation for associated anomalies:
 - Echocardiogram: should be considered if murmur is appreciated on physical exam.
 - Chest radiograph: if signs of respiratory distress are present, a chest radiograph can identify pneumothorax or pulmonary hypoplasia.

SURGICAL MANAGEMENT^{3,8}

Preoperative Planning

- Respiratory status should be optimized prior to abdominal reconstruction.
- Urinalysis without evidence of infection should be done prior to surgery.
- Nasogastric tube placed prior to operation to decompress intestinal contents.

Positioning

- The patient is placed in the supine position.
- The abdomen is prepped with antiseptic.

Approach

- Two main open exposures have been described for umbilical preservation, described by Ehrlich and Monfort.

- The Ehrlich approach⁸:
 - A midline vertical incision is made from xiphoid to pubis; an inferior transverse incision is made at the lower end of the incision. The umbilicus is left on a vascular pedicle.
 - The midline incision is carried down to the peritoneum.
 - If a urologic repair is to be performed in the same operation, this will now take place.
- The Monfort approach⁹ (**FIG 2**):
 - An elliptical incision is used to remove redundant abdominal wall skin from xiphoid to pubis.
 - The umbilicus is preserved from the full-thickness skin excision with a second incision to preserve its original location.
 - The skin and subcutaneous tissue is dissected away from the underlying fascia, exposing the lateral abdominal wall.

FIG 2 • The area of laxity where the skin will approximate is identified and excised.

TECHNIQUES

■ Ehrlich Approach

- Skin flaps are created from the midline incision laterally until the level of the midaxillary line, separating the abdominal musculature from the skin and subcutaneous tissue.⁸
- Fascial advancement is then done bilaterally until the two sides are aligned

in the midline.

- If umbilical sparing abdominoplasty is being done, the side with the umbilicus should be anterior.
- Horizontal mattress sutures are used to align the fascia.
- At this time, excess skin is excised bilaterally.

■ Monfort Approach

- Access to the abdomen is created using two fascial incisions to the epigastric arteries.⁹ If urological correction is to be done concurrently, these incisions expose the genitourinary system (**TECH FIG 1A**).
- Once the intra-abdominal portion is completed, the lateral fascia is closed by overlapping the central remaining fascia to decrease abdominal wall laxity bilaterally (**TECH FIG 1B**).

TECH FIG 1 • A. Lateral fascial incisions are made in the Monfort repair, which provides access to the abdominal cavity if urologic corrections are needed. **B.** The lateral fascia is closed by overlapping the central remaining fascia to decrease abdominal wall laxity

bilaterally.

■ Closure

- The skin and subcutaneous tissues are closed in two layers (**TECH FIG 2**).
- A drain is placed in the subcutaneous tissue and maintained to suction to prevent formation of seromas.
- The nasogastric tube is removed prior to extubation.

TECH FIG 2 • The skin is finally reapproximated in the midline, and closed in two layers.

Intraoperative monitoring

- It is important to monitor airway pressures during abdominal wall reconstruction to identify abdominal compartment syndrome.

Laparoscopy

- Laparoscopic abdominoplasty has been described and has been proposed to result in decreased rates of intra-abdominal adhesion formation. The fascia at the level of the anterior rectus muscle is plicated intra-abdominally, and then tacked to the medial fascial wall to reduce laxity.¹⁰

POSTOPERATIVE CARE

- Pain control, initially with intravenous analgesia.
- Subcutaneous drains are maintained to suction until drain output decreases, thereby minimizing the risk of seroma formation.
- An abdominal binder should be worn for 8 to 10 weeks postoperatively.
- Close monitoring of respiratory status is needed, as patients can develop respiratory distress in the postoperative period and may require intubation.

COMPLICATIONS³

- Continued abdominal wall laxity.
- Necrosis of skin flaps; close attention to blood supply of the flaps should be done to maintain adequate perfusion.
- Long-term complications can be related to urological complications.
- Overall mortality of prune belly is about 20% and is usually related to renal complications.

65 Gastroschisis and CHAPTER Omphalocele

Jamie C. Harris and Fizan Abdullah

DEFINITION

Gastroschisis

- Gastroschisis is the most common congenital abdominal wall defect in the newborn period. This results from failure of the intestines to return back into the abdomen during development around week 10 of gestation.
- The abdominal wall defect is usually less than 4 cm in diameter and is more commonly located to the right of midline.

Omphalocele

- Omphalocele is the second most common abdominal wall defect, 1/5000 live births.
- This is characterized by a large defect, greater than 4 cm, and is covered by a membrane of peritoneum.
- This can contain intestines, as well as liver, spleen, and gonads. Unlike gastroschisis, omphalocele has a high rate of associated anomalies, including chromosomal abnormalities and cardiac defects.

DIFFERENTIAL DIAGNOSIS

- Ruptured omphalocele can be distinguished from gastroschisis based on the size of the defect (greater than 4 cm), as well as contents other than intestines in the defect.
- An umbilical cord hernia will be smaller than omphalocele, and does not contain abdominal organs.
- Pentalogy of Cantrell is a rare constellation of ectopia cordis, omphalocele,

sternal cleft, anterior diaphragmatic hernia, and intracardiac defect.

- In ectopia cordis, the defect is located at the midline of the sternum and contains the heart.

Patient History and Physical Findings

- Prenatal history
 - Often, abdominal wall defects are diagnosed on prenatal screening. Maternal serum and amniotic fluid demonstrates elevated alpha fetoprotein (AFP).
 - Amniotic fluid demonstrates elevated acetylcholinesterase.
 - There is a higher specificity of elevated AFP for gastroschisis compared to omphalocele.
- Postnatal history and physical (**FIG 1**)
 - For both defects, birth history as well as patient stabilization from a cardiopulmonary standpoint should be completed first.
 - Initial inspection should be done to determine:
 - The presence of a covering membrane (indicating omphalocele) (**FIG 1A**).
 - The viability of the intestines, evidence of necrosis, atresias, or perforation.
 - Contents in the defect, including liver, gonads, and other intra-abdominal organs.
 - If these are seen without a covering membrane, ruptured omphalocele should be considered.
 - Full cardiopulmonary exam should be done to determine if there are audible murmurs appreciated, which suggest an underlying cardiac defect.
 - Examination of the rest of the body to examine for any associated anomalies should be done.
 - Omphalocele is associated with multiple different syndromes including Beckwith-Wiedemann (omphalocele, macroglossia, and gigantism), and trisomy 13, 18, and 21.¹

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Prenatal ultrasound
 - Gastroschisis
 - Prenatal ultrasound will demonstrate intestines within the amniotic fluid, outside of the abdomen.
 - This is most commonly seen around 20 weeks of gestation.²
 - Anomalies, most commonly intestinal atresias, can also be identified on

prenatal ultrasound. Bowel dilatation greater than 14 mm is predictive of atresias.¹

■ Omphalocele

- Intestinal contents will be seen outside of the abdomen.
- The sac can be visualized on ultrasound, helping distinguish from gastroschisis.
- Additionally, liver can be visualized in the defect.
- This is seen around 18 weeks of gestation.
- Evaluations of other associated anomalies, including cardiac, can be done on prenatal ultrasound as well.

■ Postnatal echocardiogram

- The rate of cardiac anomalies in omphalocele is higher (14%–47%) than in gastroschisis (3%–33%).³
- Common cardiac anomalies that are seen are ventricular septal defect, atrial septal defect, and tricuspid atresia. A complete cardiac evaluation for omphalocele should be done in the perinatal period.

SURGICAL MANAGEMENT

Preoperative Planning

■ Gastroschisis

- There are two management strategies for gastroschisis:
 - Delayed closure with silo placement, allowing for reduction of the abdominal contents over the following days
 - Immediate reduction with closure at birth

FIG 1 • A. Omphalocele presents with a membrane

covering and the umbilicus originating from this membrane. **B. Gastroschisis** presents with a defect in the abdominal wall without a membrane covering the extruded intestines.

- Many studies monitor intra-abdominal pressures for signs of abdominal compartment syndrome to guide decisions on immediate vs delayed closure.^{3,4}
- When the diagnosis is known prenatally, delivery should be done at a hospital in which pediatric surgeons can be present.
- The current guidelines have shown no difference in outcomes between vaginal delivery and cesarean section for gastroschisis. Delivery modality should be at the discretion of the obstetrician. Additionally, older gestational age is associated with less complications, where 37 weeks is considered term.⁵
- Immediately after birth, the intestines should be covered with sterile moist towels to minimize fluid losses. Intravenous access should be started to replace losses.
- Assessment of the viability of the bowel should be done.
 - If any atresias are noted, this should be documented. These are generally repaired 4 to 6 weeks after birth to allow the intestinal inflammation gastroschisis to decrease.
 - Atretic segments of intestine, if not compromised, are reduced into the abdomen.
- If necrotic or perforated intestines are encountered, termed complex gastroschisis, these are resected and enterostomies are created.
- An orogastric tube should be placed at birth to aid in bowel decompression to facilitate reduction into the abdominal cavity.
- **Omphalocele**
 - When the diagnosis is known prenatally, delivery should be done at a hospital in which pediatric surgeons can be present.
 - Surgical repair is dependent upon the size of the omphalocele. For giant omphaloceles with loss of abdominal domain, primary closure is generally not attempted. These are often complex and require a level of creativity to close. Closure methods that are used include promoting sac granulation by treating with topical agents such as diluted betadine, xeroform, or bacitracin to allow

the peritoneal sac to become firmer and more durable.

- Skin flaps and grafts, such as Gore-Tex mesh, can be used to cover the sac, and negative pressure wound VAC used to promote granulation.
- If the omphalocele is not a giant omphalocele, primary closure of the small omphalocele can be done.

Positioning

■ Gastroschisis

- The patient is positioned in the supine position, with the arms at the patient's side.
- The abdomen should be prepped and draped into the operative field.
- The surgeon is positioned on the right of the patient, while the assistant is on the left.

■ Omphalocele

- The patient is positioned in the supine position, with the arms at their sides.
- Antiseptic prep is used and should include the entire abdomen up to the chest.
- Reduction of the sac contents into the abdomen is performed at this point.

TECHNIQUES

■ Repair of Gastroschisis

Immediate Reduction

- If primary closure is feasible at the time of birth, the umbilical cord can be used to elevate the abdominal cavity to reduce the intestines within the cavity.
- Once the intestines are returned to the abdominal cavity, closure of the defect can be managed in a similar fashion with both methods.

Delayed Closure With Silo Placement

- The infant is placed supine⁶ (**TECH FIG 1**).
- The silo bag can either be spring loaded, which is placed below the fascia, or sutured to the fascia.
- The intestines are maintained in the silo.

- It is important to maintain upward traction on the silo to maintain bowel orientation and minimize any twisting or kinking of the mesentery to minimize the risk of ischemia.
- Once secured, serial reduction of the intestine within the silo is done, and complete reduction is usually accomplished within 2 to 3 days of life.
- Often, the silo can be placed with light sedation to minimize the need for general anesthesia in an infant.

Closure

- Sutured closure of the defect is done after the intestines are reduced to the abdomen.
 - The fascia is then closed using either a purse-string or interrupted suture closure.
 - The skin is closed using a running subcuticular stitch.
- Alternatively, sutureless closure has been demonstrated to be a viable option for closure^{7,8} (**TECH FIG 2**).
 - The umbilical cord remnant is cut to fit over the fascial defect.
 - The remnant is then secured in place using Tegaderm or adhesive tape to reinforce the defect.
 - Tegaderm or tape is maintained for 3 days postoperatively and is then removed.
 - The defect closes circumferentially around the umbilical cord.

TECH FIG 1 • Initial management of gastroschisis involves placing a spring-loaded silo below the fascia and the intestines are suspended. This is serially reduced over the next few days until the abdominal contents are completely reduced and closure can be completed.

Primary Closure of Omphalocele

- The sac is incised circumferentially at the level of the skin.
- Any remaining herniated intestinal contents are completely reduced into the abdomen, monitoring airway pressures as they are reduced.
- After reduction, the sac is excised and the fascia is closed primarily.
- The fascia can be closed with either interrupted fascial sutures or running fascial closure.
- If the defect is large, primary fascial closure is not feasible and temporary closures or mesh closures can be considered.⁹
- Once the fascia is closed, the subcutaneous tissue is closed in layers.
- A running subcuticular suture is used to close the skin.
- Generally, drains are not used following skin closure.

TECH FIG 2 • Sutureless closure. **A.** The intestines are reduced completely into the abdominal cavity. **B.** The umbilical cord remnant is then placed over the defect and **(C)** secured in place with Tegaderm.

PEARLS AND PITFALLS

- | | |
|----------------------|--|
| Gastroschisis | <ul style="list-style-type: none">■ 5%–8% of gastroschisis patients have intestinal atresia; therefore, careful running of the bowel should be done whenever feasible.■ Gastroschisis defects placed in a silo bag can typically be reduced over 24–72 hours. |
| Omphalocele | <ul style="list-style-type: none">■ For patients with omphalocele, maintaining the membrane and not allowing it to rupture is paramount, as the membrane provides significantly more tissue to adequately cover the defect.■ Surgical options for closure and/or temporary surgical silo are used only if it is not possible to preserve the peritoneal sac in omphalocele, or if the sac ruptures. |

POSTOPERATIVE CARE

- **Gastroschisis**
 - During intestinal reduction, observation for signs of abdominal compartment syndrome including elevated airway or bladder pressures, as well as decreasing urine output should be monitored.
 - Return of bowel function is very slow in gastroschisis, and postoperative parenteral nutrition is necessary to support the infant until oral intake can be instated.
 - If atresias are present, resection and primary anastomosis can be completed once intestinal inflammation has decreased. This usually takes place 4 to 6 days after birth.
- **Omphalocele**
 - Airway pressures as well as bladder pressures should be monitored for signs of abdominal compartment syndrome.
 - If granulation of the sac is the initial method of closure, close inspection of defects within the sac should be done regularly.
 - Management of associated anomalies should continue to be done, as these are what cause the largest morbidity in this group.

COMPLICATIONS

- Most often, complications associated with gastroschisis have to do with prematurity rather than the surgical repair.²

- Similarly, complications associated with omphalocele are most often related to the associated anomalies.
- Gastroschisis has a high rate of necrotizing enterocolitis (NEC), and the surgeon should be cognizant of this if bloody stools or abdominal distention occur in the perioperative period.
- Overall survival rates in gastroschisis are 90%; overall survival rates in omphalocele are 70% to 95%.

66 Management of the Open Abdomen

CHAPTER

Alexander F. Mericli and Charles E. Butler

DEFINITION

- The phrase “open abdomen” is used to describe a defect in the abdominal wall that exposes the viscera.
- There are several challenging clinical scenarios that can necessitate leaving the abdominal cavity opened or that can result in an open abdomen (**FIG 1**):
 - Damage control laparotomy after trauma
 - Excessive visceral edema as seen in severe abdominal sepsis
 - Following a decompressive laparotomy for management of abdominal compartment syndrome
 - Strategies involving a planned relaparotomy (second look for intestinal ischemia)
 - Staged abdominal wall reconstruction after fascial dehiscence and evisceration
- The central tenant of open abdomen management is the construction of a temporary abdominal closure until definitive abdominal wall reconstruction can be performed.
- When one is confronted with a clinical situation that requires an open abdomen or results in an opened abdomen, there is a number of reasons why it may be prudent to stage the abdominal reconstruction with a temporary abdominal closure:
 - Decreases tension on the musculofascial abdominal wall and prevents abdominal compartment syndrome
 - Reduces risk of evisceration
 - Facilitates regaining access to the abdominal cavity
 - Reduces lateral retraction of the skin, subcutaneous tissue, muscle and fascia

- Ideally, it facilitates a delayed primary abdominal wall closure.

ANATOMY

- The abdominal wall is a layered structure consisting of muscle and fascia.

FIG 1 • Various clinical scenarios commonly managed using the technique of temporary open abdomen. From left to right: open abdomen after postsurgical evisceration; multiple enterocutaneous fistulae; open abdomen associated with abdominal sepsis; open abdomen after damage control laparotomy. © Charles E. Butler, MD.

- The paired rectus abdominis muscles comprise the central portion, ensheathed in the fascia of the anterior and posterior rectus sheaths.
- The rectus muscles are flanked on either side by the oblique family of muscles: the external oblique, followed by the internal oblique, followed by the transversus abdominis.
- Above the arcuate line (approximately at the level of the anterior superior iliac spine), the anterior rectus sheath is made up by contributions from the external oblique aponeurosis and internal oblique; the posterior rectus sheath is made up by the internal oblique, transversus, and transversalis fascia.
- Below the arcuate line, there is no posterior sheath, only transversalis fascia is below the rectus muscle (**FIG 2**).

PATHOGENESIS

- The scientific rationale for the creation and maintenance of an open abdomen is centered on the phenomenon of intestinal edema and decreasing the impact of the inflammatory cascade.

- The intestine is a highly vascularized structure with a rich network of arteries, veins, capillaries, and lymphatic vessels. In pathologic states, such as after an abdominal trauma, after abdominal surgery, or in abdominal sepsis, a decrease in clearance of fluid from the extracellular space can result in swelling of the intestinal wall several times the normal diameter, potentially interfering with perfusion of the bowel.
- Multiple inflammatory cells are present within the bowel wall and peritoneal membrane.
- In the postsurgical abdomen, the trauma abdomen, and in abdominal sepsis, there is a profound local inflammatory response, which quickly progresses to systemic inflammatory response syndrome (SIRS), which can easily contribute to multiple organ dysfunction syndrome (MODS).

FIG 2 • Cross-sectional anatomy of the abdominal wall superior and inferior to the arcuate line.

- Premature closure of the abdomen can exacerbate the inflammatory response and accelerate these syndromes as well as contribute to abdominal compartment syndrome.¹
- Utilizing the open abdomen technique is associated with survival rates up to 80% after abdominal trauma, severe intra-abdominal sepsis, and acute evisceration.²⁻⁵

Abdominal Compartment Syndrome

- Abdominal compartment syndrome is a syndrome of uncontrolled intra-abdominal hypertension. Any factor that raises intra-abdominal pressure can contribute to abdominal compartment syndrome, including free blood and clots, bowel edema, vascular congestion, excessive crystalloid resuscitation, intraperitoneal packing, and nonsurgical bleeding, acidosis, hypothermia, and postoperative ileus.
- Normal intra-abdominal pressure is 0 to 5 mm Hg and can easily be quantified by measuring bladder pressure.
- Abdominal compartment syndrome is defined as a sustained bladder pressure of 20 mmHg or greater with dysfunction of 1 or more organ systems (ie, heart, lungs, kidneys, neurologic, etc.) OR a sustained bladder pressure of greater than 25 mmHg without organ dysfunction.
- Once diagnosed, emergent abdominal decompression is indicated. Typically, organ function returns to normal after decompression, but a mortality rate of 50% has been recorded, secondary to ongoing MODS.⁶

NATURAL HISTORY

- There are numerous physiologic changes that accompany an open abdomen. These changes are not insignificant and can contribute to substantial morbidity; however, the potential for morbidity of an intentional open abdomen is outweighed by the possible complications that could ensue, should the abdomen be closed prematurely.
- Fluid balance
 - A significant amount of peritoneal fluid is lost through an open abdomen, typically 1 L/h for a 70 kg person.

- If a closed suction system is used as part of the temporary abdominal closure, such as negative pressure therapy, then this fluid loss can be quantified and therefore accurately replaced.
- Maintenance of normothermia
 - The large cutaneous defect oftentimes present with an open abdomen impairs the body's thermoregulatory system.
 - The loss of peritoneal fluid exacerbates heat loss through convection.
 - Frequent temperature monitoring, forced air warming blankets, and a warmed room are all techniques that can be employed to counteract this effect.
- Protein loss
 - Peritoneal fluid is protein rich, with 2 g protein/L.⁷ This must be replaced through diet or enteral feeds in order to maintain nitrogen balance.
- Fistula
 - With the open abdomen, the bowel is at risk for injury. Patients with a fresh bowel anastomosis are at greatest risk.⁸
 - Whenever possible, the viscera should be covered by the omentum for an additional layer of protection.

FIG 3 • Anterior and lateral views of a patient with abdominal loss of domain. The rectus and oblique muscles have retracted laterally overtime. The exposed viscera is skin grafted in anticipation of delayed abdominal wall reconstruction. © Charles E. Butler, MD.

- Loss of domain
 - The creation of an open abdomen places the patient at risk for losing

abdominal domain as the musculofascial abdominal wall retracts laterally over time (**FIG 3**).

- Methods of temporary abdominal closure are designed to prevent this situation by keeping the fascia as medial as possible.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Although it is most commonly the decision of the general or trauma surgeon, it is helpful for the plastic surgeon to understand the factors that are involved in deciding whether a patient should be managed with an open abdomen.
- Trauma/damage control
 - Preoperative predictors: penetrating torso trauma with hypotension, need for resuscitative thoracotomy, blunt abdominal trauma with intraperitoneal hemorrhage, and hypotension
 - Intraoperative predictors: development of a coagulopathy, intraoperative exsanguination requiring greater than 10 units of packed red blood cells, pH less than 7.2, base deficit greater than -6 in patients older than 55 years or greater than -15 in patients younger than 55 years, temperature less than 34°C , and/or estimated blood loss greater than 4 L^2 .
- Abdominal compartment syndrome
 - Patients with sustained intra-abdominal pressure greater than 20 mm Hg with onset of new organ dysfunction
 - Patients with acutely increased intra-abdominal pressures greater than 25 mm Hg without acute organ dysfunction should be considered for prophylactic decompression.
 - Patients at high risk for development of abdominal compartment syndrome: those requiring greater than 15 L crystalloid or 10 units of packed red blood cells, patients with increased peak inspiratory pressures greater than 40 mm Hg upon fascial closure.²
- Planned relaparotomy
 - Management of intestinal ischemia potentially requiring repeat bowel resections
 - Severe abdominal sepsis necessitating repeated debridements, such as in pancreatic necrosis or intra-abdominal abscesses
- Acute postoperative evisceration
 - Fascial dehiscence in the acute or subacute postoperative period can result in evisceration. Given that this often occurs during the inflammatory stage of wound healing, visceral edema and friable, inflamed abdominal wall soft

tissue may preclude immediate fascial reapproximation.

IMAGING

- Computed tomographic imaging of the abdomen and pelvis are imperative for surgical planning and preoperative evaluation. **FIG 4** demonstrates images from a patient with an open abdomen and associated lateral musculofascial retraction (loss of domain) (left) as well as a patient with an incisional ventral hernia after laparotomy (right).

SURGICAL MANAGEMENT

- A variety of surgical techniques for temporary abdominal closure are available, ranging from a skin-only closure to the more sophisticated ABThera System (KCI, San Antonio, TX).
- The ideal temporary closure contains the viscera, minimizes skin maceration and damage to the underlying bowel or fascia, and facilitates durable fascial reapproximation. Although there are advantages and disadvantages to each technique (Table 1), the method of temporary abdominal closure is largely dependent upon surgeon preference.

Preoperative Planning

- Preoperatively, a full history should be obtained and physical exam should be performed.
- A basic laboratory panel should be obtained and preoperative CT scan should be performed.

FIG 4 • Computed tomography images from a patient with an open abdomen and associated lateral

musculofascial retraction (loss of domain) (*left*) as well as a patient with an incisional ventral hernia after laparotomy (*right*).

Table 1 Temporary Abdominal Closure Techniques

	Materials/Technique	Advantages	Disadvantages
Skin-only closure	Suture; staples	Inexpensive; fast; minimizes fluid and heat loss	100% hernia rate; high risk of evisceration; risk of abdominal compartment syndrome
Silo technique	“Bogota” bag; 3 L IV bag; suture; drains; bag secured to edges of fascia to contain viscera within “silo”	Inexpensive; visualization of intra-abdominal contents; minimizes fluid and heat loss	Risk of evisceration; loss of domain; poor fluid management
Absorbable synthetic mesh	Polyglactin 910 mesh, suture; mesh placed as bridge between fascial edges	Absorbable, can apply skin graft once granulation tissue forms over mesh	100% ventral hernia rate; risk of enterocutaneous fistula and evisceration
Bioprosthetic mesh	Acellular dermal matrix; mesh placed as bridge between fascial edges	Incorporates; low risk of infection or extrusion in contaminated settings; can be skin grafted once granulation tissue forms	Expensive; extremely high ventral hernia rate at 5 years if used in bridging format
Nonabsorbable synthetic mesh	Polypropylene; polytetrafluoroethylene patch; patch anchored to fascia laterally and serial plication of the	Extends the life span of the temporary abdominal closure;	Fascial trauma; adhesions; enterocutaneous fistula formation; compartment

	patch at the midline progressively medializes the fascial edges	inexpensive; limits loss of domain	syndrome possible if plication too aggressive
Patch	Wittmann patch (Starsurgical, Inc., Burlington, WI); two pieces of mesh approximated to lateral fascial edges, two pieces latch onto each other similar to Velcro; mesh is sequentially tightened	Limits loss of domain; high rate of primary fascial approximation; allows for extended open abdomen	Requires multiple fascial manipulations; requires special equipment; adhesions can occur to undersurface of mesh
Vacuum pack closure	Nonadherent sheet placed over bowel, followed by surgical towels, drains, and iodoform-impregnated occlusive dressing; wall suction	Inexpensive; ability to monitor fluid losses; temperature control	Poor control of domain; theoretical potential for massive exsanguination. Enterocutaneous fistula formation
Commercial negative pressure system	V.A.C. Therapy (KCI, San Antonio, TX)	Plastic-encased sponge designed to be placed in contact with the viscera; prevents adhesions; fluid management; temperature control; minimizes visceral edema; high rate of success with primary fascial reapproximation if used in	Theoretical potential for massive exsanguination. Enterocutaneous fistula formation; expensive

		conjunction with fascial retention sutures	
--	--	--	--

TECHNIQUES

■ Fascial Closure Techniques

- Fascial closure techniques use an interposition graft material sutured to the abdominal fascia to bridge the laparotomy defect.
- These techniques can utilize *absorbable synthetic* materials such as polyglactin 910 mesh, *bioprosthetic mesh* such as Strattice (Acelity, Inc.), Surgimend (TEI biosciences, Inc.), or *nonabsorbable synthetic* materials such as the Wittmann Patch (Starsurgical, Inc.), expanded polytetrafluoroethylene, or polypropylene mesh.
- Initially, the mesh material should be loose in order to allow for visceral edema.
- As the edema resolves, the mesh is either serially excised, plicated, or advanced (Wittmann patch) to facilitate fascial approximation during reexploration.
- Typically, the patient is taken to the operating room every 48 hours for repeated washouts, reexplorations, and mesh tightening until the fascia can be reapproximated primarily.
- These techniques provide a mechanism to limit or reverse the loss of domain that occurs with an open abdomen. Therefore, fascial closure techniques should be considered when the open abdomen is likely to be prolonged greater than 1 week.
- Fascial closure techniques do require suturing to the abdominal fascia, which may increase the risk of fascial injury.

Fascial Approximation Anticipated During Present Hospital Admission

- Fascial closure technique if the possibility of fascial approximation is anticipated during hospital admission: Wittmann Patch (Starsurgical, Inc.)
 - Intraperitoneal drains are placed.

- Patch sutured to fascial edges on either side of laparotomy.
- Material has hooks and eyes similar to Velcro, which facilitates repeated openings and reclosures (**TECH FIG 1**).

TECH FIG 1 • Artistic rendition of the Wittmann patch for management of the temporary open abdomen in situations where fascial approximation is anticipated during present hospital admission. Note the hooks and loops on the opposing pieces of mesh allowing sequential fascial medialization.

- The rate of primary closure for this method is 78% to 100%.⁹
- The rate of fistula is 2%.⁹

Delayed Fascial Approximation Anticipated

- Fascial closure technique if fascial approximation is likely not possible during initial hospital admission: bridged polyglactin 910 mesh or bridged

bioprosthetic mesh

- Intraperitoneal drains are placed.
- Mesh is fixed to the fascial using polydioxanone sutures, bridging the fascial defect (**TECH FIG 2A**).
- The mesh is covered with a moist dressing and changed twice daily.
- The mesh is evaluated for redundancy on a daily basis; if redundancy is present, the pleating is plicated in the midline at the bedside with running absorbable suture.
- If the fascial edges are able to be approximated to within 2 to 4 cm of each other before the formation of granulation tissue overlying the mesh, then the patient is returned to the OR for delayed primary fascial reapproximation.

TECH FIG 2 • A. Abdominal wall closure with bilateral component separation and bridged bioprosthetic mesh. **B–D.** Series of photographs demonstrating temporary abdominal closure with a split-thickness skin graft. From left to right: Due to visceral edema, fascial approximation is not possible. A bridging mesh is placed and granulation tissue forms over the mesh. Skin grafts are placed over the mesh and granulation tissue. © Charles E. Butler, MD.

- If granulation tissue forms over the mesh before fascial reapproximation is possible, then a skin graft is applied and delayed reconstruction is planned for 6 to 12 months following the injury (**TECH FIG 2B–D**).
- In this scenario, bioprosthetic mesh may have several advantages over polyglactin 910, including a greater tensile strength and structural support

of the abdominal wall comparatively. The disadvantages include expense and difficulty to plicate at the bedside. Therefore, if a biologic is used, it should be inset with sufficient tension. Similarly, it too can be skin grafted once granulation tissue has formed.

Negative Pressure Wound Therapy for Temporary Abdominal Closure

- Negative pressure stimulates cell division, angiogenesis, and cell proliferation.^{10,11}
- Negative pressure for temporary abdominal closure was first described by Barker and colleagues.¹² They described a system in which a fenestrated plastic draped was placed in contact with the viscera, followed by surgical towels and drains; this middle layer was then covered by a bioocclusive adhesive sheet (Ioban). The drains were then connected to the wall suction at -150 mm Hg. Using this system, the authors achieved a primary fascial reapproximation rate of 55.4%. Fistula rate was 4.5%. The authors describe that within 7 to 10 days, the bowel would adhere to the abdominal wall, preventing primary reapproximation. Therefore, if definitive abdominal wall closure could not be achieved within 7 to 10, then the bowel should be skin grafted and definitive closure planned for 6 to 12 months.
- There are now several commercially available options for negative pressure management of the open abdomen. The most studied and popular system is the VAC System by KCI, Inc. (San Antonio, TX).
- The VAC System consists of an inner plastic-encased sponge designed to be in direct contact with the viscera. The plastic interface protects the bowel, prevents adhesion formation, and is perforated to allow drainage of peritoneal fluid.
- Next, a macroporous polyurethane sponge is then applied over the inner layer and is in direct contact with the overlying fascia and subcutaneous tissues.
- Fascial retention sutures can then be placed, if desired, to further medialize the fascial edges.
- The entire construct is then covered with an occlusive dressing and the machine is set to -125 mm Hg (**TECH FIG 3**).
- The patient is returned to the operative room every 2 to 3 days for irrigation, debridement, negative pressure dressing change, and further fascial medialization.

- Primary fascial closure rates using this system average 67%⁹ but can achieve 100% with the adjunctive use of fascial retention sutures.¹³
- Fistula rate is 2.9%.

TECH FIG 3 • Negative pressure therapy for management of the open abdomen. A sterile fenestrated plastic drape is placed over the exposed viscera, followed by a macroporous sponge, and covered with an occlusive plastic dressing. © Charles E. Butler, MD.

PEARLS AND PITFALLS

Physiologic rationale for temporary abdominal closure?

- Premature closure of the abdomen can exacerbate the inflammatory response and accelerate SIRS and MODS as well as contribute to abdominal compartment syndrome
- Utilizing the open abdomen technique is associated with survival rates up to 80% after abdominal trauma, severe intra-abdominal sepsis, and acute evisceration

When to consider temporary abdominal closure?

- Laparotomy for intra-abdominal trauma
- Abdominal compartment syndrome
- Abdominal sepsis
- Planned relaparotomy

	■ Acute evisceration
What are the two main methods of temporary abdominal closure?	■ Progressive fascial closure techniques ■ Negative pressure wound therapy
Postoperative care	■ Intensive fluid management due to insensible losses associated with open abdomen ■ Nutrition and protein intake ■ Return to the operating room every other day for repeat debridement, dressing change, and integral fascial advancement

POSTOPERATIVE CARE

- Because of the physiologic derangement that is associated with the clinical conditions necessitating an open abdomen, these patients often require intensive care.
- Postoperatively, the focus should be on resuscitation, fluid and electrolyte management, and nutrition. There is a multitude of information available on these topics, a review of which is outside the scope of this chapter.
- Time interval for repeated debridements
 - Regardless of the technique of temporary abdominal closure, the patient is typically returned to the operating room every 2 or 3 days.
 - There are no data to support a specific interval, and every clinical situation is different.
 - A shorter interval between episodes of general anesthesia may be physiologically challenging for the patient, whereas a longer period will allow for the formation of intestinal adhesions, increasing the risk for enteral injury.
- Nutrition
 - Assuming there are no contraindications (enteral anastomosis, ileus), enteral nutrition can and should continue during the period of open abdomen and temporary abdominal closure.
 - Because of the necessary repeated trips to the operating room, it can be difficult to meet nutritional requirements; therefore, a combination of both enteral and parenteral nutrition is prudent.
- Neuromuscular blockade

- A short course of neuromuscular blockade may decrease fascial edge retraction and be a useful adjunct to negative pressure devices.
- In one study, 192 open abdomen patients were divided into two groups: one receiving a continuous infusion of a neuromuscular blocker for greater than 24 hours and one receiving standard care.
- The patients receiving the neuromuscular blockade were more likely to achieve primary fascial closure by 7 days (93% vs 83% $P < .024$) and had no increase in pneumonia.¹⁴
- Antibiotics
 - There is no evidence for prophylactic administration of antibiotics in patients with open abdomens other than the typical perioperative prophylactic antibiotic dosing.
 - Antibiotic use and duration should be determined by the treatment appropriate for the primary abdominal pathology (ie, abdominal sepsis, abscess, etc.).
- Sedation and analgesia
 - There are no studies regarding optimal pain control or sedation in patients with an open abdomen.
 - Epidural anesthesia has been shown to reduce intra-abdominal pressure and pain control in patients with open abdomen due to abdominal compartment syndrome.¹⁵

OUTCOMES

- Once the indication for open abdomen has resolved, a delayed primary abdominal wall reconstruction should be performed as soon as possible.
- Delayed primary closure of the abdominal wall is most possible if performed within 8 days of initial open abdomen.^{16,17} A recent study of the damage control population demonstrated that delayed primary abdominal closure is only possible in 65% of patients.⁹
- If negative pressure temporary closure is combined with fascial retention sutures, a 100% primary repair rate can be achieved.¹³
- In situations where delayed primary abdominal closure cannot be obtained, a bridged biologic or synthetic absorbable mesh repair is performed, followed by skin grafting over the mesh once granulation tissue has formed. This controlled ventral hernia is then repaired 6 to 12 months later.¹⁸
- In certain clinical scenarios, the iatrogenic creation of a ventral hernia with

skin graft coverage is not in the patient's best interest. For instance, in the oncologic population, a durable soft tissue reconstruction must be established expeditiously so that the patient can proceed with adjuvant radiation and chemotherapy.

- In these situations, adjunctive abdominal wall reconstruction techniques can oftentimes be employed to achieve primary fascial reapproximation in the acute setting.
- These techniques are covered in other chapters and include component separation, the use of inlay mesh, and various autologous flaps.

COMPLICATIONS

- The open abdomen leads to fluid and electrolyte derangements that must be actively monitored and corrected. The prolonged open abdomen, bowel fistulization, and loss of abdominal domain can complicate management. The main goal of temporary abdominal closure is fluid management and minimizing the loss of domain.
- Methods of temporary abdominal closure are associated with a bowel fistulization rate of 2% to 4.5%. Factors that increase the likelihood of fistula are abdominal sepsis, bowel anastomosis, and negative pressure therapy in direct continuity with a new bowel anastomosis.
- If using a "fascial closure technique," primary fascial approximation should be achieved within 7 to 12 days; otherwise, the formation of intestinal adhesions may necessitate a delayed closure approach at a later date.
- If using a modern negative pressure technique, such as the ABThera System, primary fascial approximation can be achieved over a longer period of time, up to 30 days.
- Temporary abdominal closure techniques result in primary fascial approximation in 65% to 100% of patients. In the 35% of patients where primary fascial approximation is not possible, then either a delayed closure approach is taken (skin grafting followed by abdominal closure at a later date after the resolution of inflammation), an adjunctive abdominal reconstruction technique is utilized (component separation, flap), or some combination of both.

CHAPTER Umbilicoplasty

Sergey Y. Turin, Chad A. Purnell, and Gregory A. Dumanian

DEFINITION

- Reconstruction of the umbilicus is an essential part of restoring the natural aesthetic of the abdomen.
- It is the focal point of the anterior abdominal wall, helps define the middle abdominal sulcus and if absent or malformed, will draw attention to the abdomen.¹
- We present two simple techniques for creation of a neoumbilicus.
 - One is to be used for patients with vertical midline incisions.
 - The other is for patients undergoing abdominoplasty when the umbilical stalk cannot be maintained.
- Umbilicoplasty for a scarred umbilicus after a standard abdominoplasty will also be discussed.

ANATOMY

- The umbilicus is generally described as a depressed circular indentation approximately 1.5 to 2 cm in diameter positioned in the midline of the abdomen at the level of the superior iliac crests² (**FIG 1A**).
- The vertical position has also been variably described as 30% to 47% of the way up between the symphysis pubis and the xiphoid.^{3,4}
- The aesthetic ideal of the female umbilicus has been described as T or vertical in shape with a superior hood or shelf.¹ Protrusion, transverse orientation, or excessive size are rated as less attractive. There is a linear depression running from the xiphoid to the umbilicus, and this compares to the smooth contour of skin without a depression from the umbilicus to the symphysis pubis. Surrounding the umbilicus is a zone of decreased fat approximately 3 cm in

diameter total, and this fat thickens to its maximum dimension for the ventral abdomen over the anterior rectus fascia.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Past surgical history, including prior transection of the umbilical stalk at the time of an umbilical hernia repair, must be obtained. Prior laparoscopy umbilical portal sites can be the cause of incisional hernias and scar formation around the umbilicus.
- A reversed sit-up maneuver should be done for evaluation of rectus diastasis.
- Significant abdominal hirsutism should be appreciated preoperatively and is a relative contraindication to umbilicoplasty, as hair-bearing skin is placed deep against the abdominal wall and could create an iatrogenic pilonidal cyst.

FIG 1 • **A.** Location of umbilicus. **B.** T-shaped umbilicus. **C.** Aesthetic abdominal contour with supraumbilical depression.

SURGICAL MANAGEMENT

Preoperative Planning

- The decision-making process for umbilicoplasty begins in the operating room after repair of the rectus muscles in the midline. The critical issue is whether or not the umbilical stalk remains vascularized and attached to the abdominal wall. For midline laparotomies, there is typically skin excess, and we find it easier to discard a marginal umbilical stalk and simply reconstruct it with pumpkin-teeth flaps.
- Patients undergoing an abdominoplasty where the stalk will not remain viable will need to be counseled that the reconstructed umbilicus with local flaps is not as aesthetic as the umbilical stalk that they currently have.

Positioning

- The patient is positioned in the usual supine position. The entire abdomen from xiphoid to pubis should be prepped to allow accurate determination of the midline and landmarks for appropriate umbilicus positioning.

TECHNIQUES

■ Umbilicoplasty in the Setting of a Midline Incision

Video p8-c067

- Once the abdominal wall is reapproximated in the midline, we assess the amount of skin redundancy and if the umbilical stalk is still connected to the abdominal wall. In the majority of abdominal wall reconstructions, the skin is redundant and requires removal to decrease dead space and improve healing. The markings for what we term “pumpkin-teeth” flaps are made at the time of this vertically oriented skin excision (**TECH FIG 1A–C**).

TECH FIG 1 • Markings for “pumpkin-teeth” flaps as

final step in abdominal wall reconstruction.

- Vertical lines from the xiphoid to the pubis are drawn to outline the midline skin to be excised. Rectangular flaps 2 cm in height and 2 cm wide are drawn and preserved in the desired location of the neoumbilicus. The flaps are excised fairly thinly, with minimal dermal fat remaining attached. After incising these pumpkin teeth, the full-thickness vertical incision for the length of the abdominal skin closure is then completed.
- We also perform a small amount of excision lipectomy just superior to the site of the neoumbilicus to allow for a depression in that area—this provides an aesthetically pleasing contour to the umbilicus.
- As the closure progresses, two 3-way sutures between the edges of the flaps and the final planned position of the neoumbilicus on the abdominal wall are placed and then tied using a 3-0 polydioxanone suture. The remaining dermal sutures are then placed in standard fashion, “folding in” these pumpkin-teeth skin flaps as the neoumbilicus (**TECH FIG 2**).

TECH FIG 2 • Postoperative result for “pumpkin-teeth” flaps.

■ De Novo Umbilicoplasty Without a Midline

Incision

- For situations when the native umbilicus is removed and there is no vertical midline incision but still some laxity in the transverse plane, we present a variation on the technique described above (**TECH FIG 3A**).
- Two laterally based rectangular flaps are incised, and the fat deep to this entire area for a diameter of 3 cm is excised. These rectangular flaps are then sewn down to the abdominal wall with 3-0 polydioxanone sutures.
- For closure of the donor site, again A is brought to A prime, and B is brought to B prime. This creates excessive tissue above and below the neoumbilicus, which is handled as two separate W-plasties. The hashed triangles are excised, and point C and C prime are sewn down to the abdominal wall to create a circular depression (**TECH FIG 3B–E**).

TECH FIG 3 • A. Umbilicoplasty design showing the initial H-shaped incision; excision of the redundant triangles of skin (shaded in); final closure design. **B.** Skin incised and approximated in midline, excess skin excised as W-plasties. **C.** Skin flaps tacked down to abdominal wall. **D.** Result at the end of the surgical procedure. **E.** Postoperative result.

■ Umbilical Stenosis After Abdominoplasty

- The goal of this umbilicoplasty is to bring the abdominal skin down to healthy umbilical stalk remnants (**TECH FIG 4**).
- In the office, the pinhole umbilicus opening is probed to ensure that a viable umbilicus stalk exists deep. The area around the scarred pinhole umbilicus opening is injected with 10 cc of xylocaine with epinephrine.
- The circular umbilical scar is excised.
- A 3-cm ring of fat is excised, especially superiorly, both to assist in local closure as well as to better identify the viable umbilicus stalk.
- The stalk is freed of scar tethering it to the abdominal wall and is mobilized superficially. The inferior aspect of stalk is opened in the Heineke Mikulicz fashion to enlarge the circular suture line.
- The closure is performed in one layer with 5-0 polypropylene sutures to the abdominal skin.

TECH FIG 4 • Umbilical stenosis after full abdominoplasty.

PEARLS AND PITFALLS

Patient selection

- Umbilicoplasty is not to be performed in hirsute skin, as this will bring hair-bearing skin deeply and create an iatrogenic pilonidal sinus.

Technical considerations	■ These procedures require a transverse excess of skin. If the skin is tight transversely, the umbilicoplasty will be pulled open. ■ Umbilicoplasties tend to drain for 1–2 weeks after creation. ■ Optimal appearance will include a depression of fat in the midline from the umbilicus to the xiphoid (see FIG 1C).
Scarred umbilicus	■ Treatment of a scarred umbilicus after abdominoplasty will require pressure on the circular scar with a marble or equivalent daily to stretch and maintain patency of the stalk.
Stenosis of the neoumbilicus	■ This may occur after inseting the umbilicus in an abdominoplasty or with a de novo umbilicus. Stenting is the first-line management options and can be accomplished with daily use of a Vaseline-impregnated gauze bolster or even a firm noise-reducing ear plug for the 1–2 months following reconstruction.⁵
Umbilicus malposition in sagittal or coronal planes	■ This occurs especially when skin is extremely redundant as in cases of massive weight loss. Preoperative placement of staples 10 cm from the midline aids in having the final skin closure in the midline.

POSTOPERATIVE CARE

- We encourage the patients to gently wash these closures with soap and water twice daily and to cover them with a dry gauze for cleanliness.

OUTCOMES

- Creation of a neoumbilicus at the time of a midline hernia repair is reliable and significantly improves appearance. Pumpkin-teeth flaps tack the skin down to the abdominal wall as an ultimate “quilting” suture to help limit seroma formation. The only complications have been excessive hair growth in males, and one female patient where the umbilicus lost its depth due to a lack of transverse skin laxity.

COMPLICATIONS

- Drainage has on occasion lasted for several weeks after umbilicoplasty. Although difficult to quantify, on occasion, there has been restenosis of the scarred umbilicus after umbilicoplasty.

Section XVIII: Perineum

68

CHAPTER Hypospadias Repair

Christopher D. Morrison and Earl Y. Cheng

DEFINITION

- Hypospadias is defined as a ventrally located meatus proximal to its expected orthotopic location.
- Hypospadias is often associated with chordee, an abnormal ventral curvature of the penis.
- The prevalence of hypospadias is estimated at 1 per 200 to 300 live births, and the prevalence appears to be increasing.^{1,2}

ANATOMY

- The hypospadiac meatus can be located anywhere along the course of the urethra:
 - Posterior/proximal: perineal, scrotal, penoscrotal
 - Middle: along the shaft of the penis
 - Distal/anterior: subcoronal, glandular
- In general, a more proximal hypospadiac meatus is associated with a more significant degree of chordee.
- The glans can vary in size, and the urethral plate can range from grooved to completely flat.
- In most cases, the prepuce does not extend ventrally, resulting in a noncircumferential dorsal hooded foreskin.
- The skin overlying the ventral aspect of the urethra can be dysplastic or insufficient, leading to ventral tethering of the penis.
- The corpus spongiosum diverges laterally or is completely atretic, which can result in a urethra that is only covered by a very thin layer of ventral skin.

PATHOGENESIS

- Hypospadias results from the incomplete development of the penis and urethra between 8 and 14 weeks gestation.
- Tubularization of the urethra is thought to be androgen mediated, and disruption of this process results in a hypospadiac meatus.³
- Both genetic and environmental factors have been associated with hypospadias.⁴
 - Hypospadias is heritable and can be associated with several syndromes (less than 10% of cases).
 - Over 20 genes have been implicated in the pathogenesis of hypospadias.
 - Environmental factors such as maternal medication/drug use, maternal age, maternal obesity, and placental insufficiency have been associated with hypospadias and may account for the rising prevalence of hypospadias.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Hypospadias is typically recognized at the time of birth during newborn examination.
- Newborn circumcision (if desired) is contraindicated in the setting of hypospadias because the foreskin may be needed for surgical repair of the hypospadias.
- History
 - A complete prenatal and family history should be performed to identify possible contributing factors.
 - If possible, ask the parents about the direction and strength of the patient's urinary stream, as well as the curvature of the penis with erections. A downward deflected urinary stream or significant curvature of the penis may affect the patient's urinary and sexual function later in life.
- Exam
 - Penile exam:
 - Location and appearance of the meatus
 - Quality and depth of urethral plate
 - Size and configuration of the glans
 - Degree of chordee
 - Integrity of the ventral skin
 - Amount of dorsal hooded foreskin available
 - A careful scrotal and inguinal exam should be performed to look for other

abnormalities such as cryptorchidism, hydrocele, or hernia.⁵

- If a patient also has undescended testicles (unilateral or bilateral), it is important to consider the possibility of a disorder of sex development (DSD).
 - If undiagnosed, a DSD condition such as congenital adrenal hyperplasia (CAH) can be life threatening.
 - These patients should undergo an endocrine workup and karyotype.
 - Approximately 20% to 30% of patients with hypospadias and cryptorchidism will have a karyotype abnormality.³
 - The most common DSD seen in patients with hypospadias and cryptorchidism is mixed gonadal dysgenesis.

IMAGING

- Proximal hypospadias can be associated with renal anomalies. However, routine imaging is not performed in most cases of hypospadias. If the patient has a severe proximal hypospadias, one could consider obtaining a renal ultrasound.

NONOPERATIVE MANAGEMENT

- For patients with distal/anterior hypospadias in which the urinary stream is relatively straight and there is no significant chordee, surgical correction is generally considered optional and is usually performed more for appearance and psychosocial reasons rather than for correction of a functional need.
- There is controversy among some urologists as to whether correction of distal hypospadias confers long-term benefits for patients.
- A 1995 study of 500 men found great variability in the meatal location. Thirteen percent of these men had anterior hypospadias with no functional compromise, and two-thirds of these patients were unaware of their hypospadiac condition.⁵
- In contrast, a 2014 study examined the self-reported outcomes for patients who had uncorrected hypospadias and found that these patients were more likely to have worse voiding symptoms, more penile curvature making sexual intercourse difficult, and worse satisfaction with the appearance of their penis.⁶

SURGICAL MANAGEMENT

- Multiple different surgical techniques have been described for distal hypospadias, including the MAGPI and the Mathieu repair. However, the

tubularized incised plate (TIP) urethroplasty, as described by Snodgrass, is the technique that is now most commonly performed by hypospadias surgeons. It is suitable for patients with a sufficiently healthy and wide (greater than 7 mm) urethral plate and less than 30-degree chordee.

- Midshaft hypospadias is often approached similarly to distal hypospadias; however, it tends to be associated with more significant chordee.
 - If there is less than 30-degree chordee and the urethral plate is sufficiently healthy and wide, a TIP urethroplasty can be performed.
 - If there is less than 30-degree chordee but the urethral plate is too narrow, hypospadias repair can be performed using a transverse preputial island flap or an inner preputial inlay graft.
- Proximal hypospadias repair presents a greater challenge for several reasons:
 - There is a longer length of urethra that must be tubularized.
 - The urethral plate may be narrow, fibrotic, or even nonexistent.
 - There tends to be a more significant degree of chordee.

Preoperative Planning

- If diagnosed at the time of birth, most urologists will delay treatment until the child is 6 months of age to decrease potential anesthetic risks.
 - Ideally, the surgery should be performed prior to the child being old enough to remember the surgery.
 - Many advocate hypospadias repair between 6 and 12 months of life.⁷
- Historically, hormonal stimulation with testosterone, dihydrotestosterone, or human chorionic gonadotropin was given preoperatively to increase penile length, glans circumference, and vascularity as this was thought to aid in surgical correction.
 - However, there is now concern that hormonal stimulation may affect normal wound healing and may lead to an increased risk of postoperative complications.⁸
 - Nevertheless, hormone stimulation is still felt to be beneficial in more severe cases of hypospadias.

Positioning

- After the induction of general anesthesia, if possible, a caudal anesthetic block is recommended for perioperative pain control.
- The patient is positioned supine for the surgery.

Approach

- The operative approach varies based on the following:
 - Location of the hypospadiac meatus
 - Severity of chordee
 - Characteristics (width, depth, and health) of urethral plate
 - Quality of penile shaft and dorsal hood skin
 - Surgeon preference/experience
- The main components of a hypospadias repair consist of the following:
 - Evaluation and correction of chordee
 - Urethroplasty
 - Glanuloplasty
 - Skin coverage
- Hypospadias repair is typically performed with the use of 2.5 times surgical loupes or with an operating microscope.
- Hypospadias repair can be either a one- or two-staged repair. The decision to perform a one- or two-stage repair depends primarily on the degree of chordee and the health of the urethral plate.
 - If the chordee can be corrected with dorsal plication and the urethral plate is healthy and wide, a TIP urethroplasty should be performed.
 - If the chordee can be corrected with dorsal plication but the urethral plate is NOT healthy and wide, the surgeon can perform either a one-staged preputial onlay island flap urethroplasty or a two-staged inner preputial inlay graft with subsequent tubularization.
 - If division of the urethral plate is required for correction of chordee, this should be performed during the initial stage. The urethroplasty should be performed in a second stage at least 6 months later.
- An algorithm for intraoperative decision-making during hypospadias repair is presented in **FIG 1**.

FIG 1 • Algorithm for hypospadias repair.

TECHNIQUES

■ Tubularized Incised Plate Urethroplasty for Distal Hypospadias Repair

■ Examination Under Anesthesia

- Prior to beginning the surgery, examine the anatomy.
- Visually inspect the meatus.
- Calibrate the meatus with bougies and examine the ventral penile skin overlying the urethra.
- If the urethra and overlying skin is too thin, it may be necessary to perform a cutback procedure to healthier tissue and perform a more proximal hypospadias repair.
- Examine the urethral plate for width, depth, and overall health.

■ Initial Approach (TECH FIG 1)

- Place a 4-0 Ethibond suture longitudinally at the tip of the glans for retraction purposes.
- Make a reverse chevron incision on the dorsum of the penis to preserve the mucosal collar flaps.
- Working laterally to medially, carefully elevate the ventral skin off of the urethra. (Avoid incising into the urethra. If necessary, it is better to buttonhole the overlying skin than to incise into the native urethra.)
- Deglove the penis down to the penopubic and penoscrotal junction.
- Induce an artificial erection and evaluate degree of chordee by constricting the corpora cavernosa at the base of the penis with a tourniquet device (ie, rubber band, dental roll, and hemostat) and injecting saline through a small-gauge butterfly needle into the corpora cavernosa.

TECH FIG 1 • Initial incisions. **A.** Reverse chevron incision to preserve mucosal collars (*arrows*). **B.** Elevation of skin off of urethra behind hypospadiac meatus (*arrow*). **C.** Example of thin ventral urethra (*arrow*) that will require cut back.

■ Correction of Chordee With Dorsal Plication

- In most cases of distal hypospadias, degloving of the penis alone will adequately straighten the penis.
- In cases in which residual chordee remains that is less than 30 degrees, this can be corrected with dorsal plication (**TECH FIG 2**).

- Dorsal plication will shorten the penis and should be avoided in patients with a small phallus.

TECH FIG 2 • Dorsal plication. **A.** Artificial erection to assess chordee (less than 30 degrees). **B.** Dorsal incision at 12 o'clock (*arrow*; between neurovascular bundles). **C.** Plication suture (*arrow*) with 3-0 Ethibond suture. **D.** Corrected chordee following dorsal plication.

- Make an incision in Buck fascia at the 12 o'clock position over the dorsal vasculature.
- Place a 3-0 or 4-0 Ethibond suture (Ethicon Inc., Somerville, NJ) parallel to the shaft, ensuring not to injure the neurovascular bundles laterally.
- Imbricate Buck fascia over the plication suture using interrupted 6-0 PDS.

■ TIP Urethroplasty (TECH FIG 3)

- Elevate the spongiosum and create glans wings.
 - Often, the corpora spongiosum can be identified diverging lateral to the urethral plate.
 - If easily identified, elevate the divergent spongiosal tissue off the corporal bodies.
 - The corpus spongiosum can be used as an additional layer of closure over the urethral repair.
 - To create glans wings, incise along the lateral borders of the urethral plate to the top of the glans.
 - Dissect down to the corporal bodies.
 - Ensure that the glans wings are sufficiently wide to allow midline approximation without tension.
- Incise the urethral plate and tubularize the urethra (TECH FIG 3B,C).
 - Make a longitudinal incision at the base to deepen the groove.
 - Place a urethral stent (size varies based on urethral diameter, usually 6–8 French).
 - Close the urethra in two layers with a 7-0 PDS suture in a running subcuticular fashion with careful attention to turn in the epithelial edges.
 - Take care to not make the neomeatus too tight.
 - If the divergent spongiosal tissue was identified and easily mobilized, reapproximate over the urethral repair using interrupted 7-0 Vicryl sutures.

TECH FIG 3 • Distal hypospadias repair with TIP urethroplasty. **A.** Preoperative examination reveals coronal hypospadiac meatus (*white arrow*) and blind urethral dimple (*black arrow*). **B.** Incision of urethral plate (*arrow*). **C.** Urethroplasty repair (*arrow*). **D.** Harvesting of dartos flap. **E.** Overlying urethral repair with dartos flap. **F.** Hypospadias closure.

- The dartos flap is used as an additional layer of coverage over the urethral repair and can be harvested from either the ventral or dorsal penis, but typically, the dorsal dartos is more supple and better vascularized (**TECH FIG 3D,E**).
- Rotate the dartos flap over the urethral repair and suture in place using 7-0 Vicryl sutures.
- Close the glans in two layers. Use 6-0 PDS (Ethicon, Somerville, NJ) to close the deep layer and 7-0 Vicryl (Ethicon, Somerville, NJ) to close the superficial layers.
- For skin closure, transpose the mucosal collar flaps ventrally, excise the redundant tissue, and suture together with 7-0 Vicryl (**TECH FIG 3F**).
- If there is inadequate ventral skin for closure, mobilize flaps from the excessive dorsal preputial skin, transpose the flaps ventrally, and suture in place with 7-0 Vicryl.
- Secure the stent to the glans with two 6-0 Vicryl sutures.

■ Midshaft Hypospadias Repair

■ Transverse Preputial Island Flap (TPIF)

- Performed in a single-stage repair.
 - The urethral plate is preserved as the posterior urethral wall and a TPIF is used to make up the anterior wall of the neourethra.
 - Harvest a strip of skin from the inner preputial skin along its native blood supply.
 - Rotate the flap ventrally and position over the urethral plate to form the anterior urethral wall.
 - Suture the skin flap to the lateral edges of the urethral plate using a running 7-0 Vicryl suture.
 - Complete hypospadias repair as previously discussed (glanuloplasty, skin coverage, etc.).
-

■ Inner Preputial Inlay Graft (TECH FIG 4)

- An inner preputial graft is used to augment the urethral plate by placement of the graft into the defect that results following incision of the urethral plate.
- Measure the dimensions of the existing urethral plate to assess the length and width of an inlay graft needed for tubularization.
- Harvest an inner preputial graft of appropriate size.
- Defat the graft.
- Apply the tourniquet to reduce bleeding.
- Make a deep incision within the native urethral plate from the hypospadiac meatus to the tip of the penis.
- Elevate the urethral plate off the underlying corporal bodies.
- Place the inner preputial graft along the vascular bed and quilt it with 7-0 Vicryl sutures.
- Mature the graft to the surrounding urethral plate tissue with interrupted 7-0 Vicryl sutures.
- Fenestrate the graft with a micro knife to prevent hematoma formation beneath the graft.
- Following placement of the graft, one can perform a single-stage repair in which the lateral aspect of the urethral plate on each side of the graft is tubularized. Alternatively, one can perform a two-stage repair in which tubularization is delayed for 6 months later to allow maturation and

neovascularization of the graft prior to creation of the neourethra. At our institution, we generally favor a two-stage approach in this setting.

- Rotate the mucosal collar flaps ventrally alongside the urethral plate and suture with 7-0 Vicryl sutures.
- The graft is allowed to heal for 6 months and then is tubularized during the second stage.
- If there is greater than 30-degree chordee such that dorsal plication is insufficient to correct the curvature, the hypospadias repair should be approached similarly to that of a proximal hypospadias.

TECH FIG 4 • Proximal hypospadias repair with inner preputial graft (first stage). **A.** Proximal hypospadiac meatus (*arrow*), narrow unhealthy urethral plate, moderate depth of glans groove. **B.** Degloving penis while preserving mucosal collars (*arrows*). **C.** Harvesting inner preputial graft. **D.** Deep incision of urethral plate (*arrow*). **E.** Elevation of lateral urethral

plate (*arrow*) off the corporal bodies. **F.** Preputial graft overlying incised urethral plate. **G.** Graft sutured into place.

■ Proximal Hypospadias Repair

- Both one- and two-stage repairs for proximal hypospadias have been described.
- In most cases, there is significant (greater than 30 degrees) chordee that cannot be corrected with dorsal plication. Consequently, a two-stage repair is most often needed for proximal hypospadias repair.
- One-stage repair is reserved for the rare cases in which there is minimal chordee that can be corrected with dorsal plication.
- If the urethral plate is healthy and sufficiently wide (greater than 7 mm), a TIP urethroplasty can be performed.
- If the urethral plate is healthy but too narrow to tubularize, a one-stage repair can be performed with a transverse preputial island flap or an inner preputial inlay flap, as described for midshaft hypospadias repair.
- Two-stage repair is recommended for patient with significant chordee and/or an unhealthy urethral plate.
 - The goal of the first stage is to correct the chordee and/or augment the urethral plate for tubularization at the second stage.

■ Stage 1: Correction of Chordee

- If there is greater than 30-degree chordee, dorsal plication is usually insufficient and the following techniques should be used to correct the curvature.

Division of Urethral Plate

- Make a transverse incision in the urethral plate at the level of the maximal curvature.
- Elevate the urethra off the corporal bodies.
- Excise dysgenetic tissue away from the corporal bodies.
- Repeat artificial erection. If chordee is now less than 30 degrees, proceed with dorsal plication.

Deep Transverse Incisions of Tunica Albuginea (DTITA)

- If significant chordee still remains that is more than 30 degree despite division of the urethral plate, the next step is to make multiple nearly full-thickness incisions in the tunica albuginea at the level of the maximal curvature.
- No full-thickness incisions into the erectile tissue should be made and thus should not affect future erectile function.
- For severe chordee, DTITA is often insufficient and corporal body grafting is necessary.

TECH FIG 5 • Division of urethral plate with corporal body grafting. **A.** Significant chordee after degloving. **B.** Chordee persists despite division of urethral plate. **C.** Corporal body incision (*arrow*) with subsequent defect. **D.** SIS grafting (*arrow*) of corporal body defect.

Corporal Body Grafting (**TECH FIG 5**)

- Make a full-thickness ventral incision through the tunica albuginea at the area of greatest curvature and extend to the lateral borders of the neurovascular bundles.
- Elevate the corporal wall off of the underlying erectile tissue to create a

diamond-shaped defect.

- Graft the defect with either a dermal graft (harvested from the inguinal area) or small intestine submucosal (SIS) (off-the-shelf xenograft material).
- Suture the graft in place with a running 6-0 PDS.

Bridging of Urethral Plate Defect

- Following division of the urethral plate and correction of chordee, it is necessary to bridge the gap between the proximal and distal native urethral plates.
- Traditionally, this is performed utilizing Byars flaps. However, at our institution, we favor an inner preputial skin flap.
- Byars flaps (**TECH FIG 6**)
 - Make a midline dorsal incision in the preputial skin.
 - Rotate each preputial skin flap (Byars flap) ventrally along with their respective dartos vascular pedicles.

TECH FIG 6 • Byars flaps using ventrally rotated preputial flaps.

- Bring the flaps together in the midline and interpose the combined Byars flaps between the proximal and distal urethral plate. If the urethral plate in the glans is flat and insufficient, the plate can be incised and the Byars flaps can be placed into the defect with extension of the flaps out to the tip of glans.
- Suture the flaps in place utilizing 7-0 interrupted Vicryl sutures.
- At the time of the second stage, the Byars flaps are tubularized to form the

urethra.

- Because of the nature of the preputial skin used for Byars flaps, the resultant tubularized urethra can be more prone to be hypermobile or difficult to catheterize. Furthermore, in our experience, the patient is more prone to urethral diverticula formation. Thus, we have favored use of an inner preputial skin flap for bridging of the urethral defect.
- Inner preputial skin flap (**TECH FIG 7**)
 - Harvest an appropriate-sized flap from the dorsal inner preputial skin while preserving the blood supply from the dartos fascia.
 - Defat the distal one-third of the flap while maintaining the blood supply to the proximal two-thirds.
 - Incise the glans urethral plate.
 - Inlay the defatted distal one-third of the flap into the incised distal urethra.
 - The proximal two-thirds of the flap is positioned along the shaft of the penis.
 - The flap is quilted to the tunica albuginea utilizing interrupted 7-0 Vicryl sutures.
 - Fenestrate the flap to reduce subcutaneous hematoma formation.
 - The urethra is tubularized at the time of the second-stage repair.

TECH FIG 7 • Division of urethral plate with preputial inlay flap. **A.** This curvature of more than 30 degrees required division of the urethral plate. **B.** Harvested preputial inlay flap. **C.** Defatted distal third of preputial flap (*arrow*). **D.** Preputial inlay flap quilted to tunica albuginea.

■ Stage 2: Tubularization of the Urethra and Glanuloplasty

- Tubularization
- Deglove the penis.
- Induce artificial erection and ensure that any previous significant chordee has been corrected.
- Make parallel incisions along the inlay graft and residual urethral plate from

the level of the hypospadiac meatus to the distal aspect of the glans.

- Tubularize the urethral plate over a 6 or 8 French stent and close in two layers, with interrupted 7-0 PDS for the first layer and a running subcuticular 7-0 PDS for the second layer.
- If available, harvest a vascularized dartos flap from the dorsum and transpose over the repair with interrupted 7-0 PDS.

Tunica Vaginalis Flap

- If a vascularized dartos flap is insufficient, harvest a tunica vaginalis flap.
- Make a transverse scrotal incision over either the left or right scrotum.
- Create a subdartos pouch.
- Deliver the testicle.
- Harvest a rectangular tunica vaginalis flap large enough to completely cover the length of the repair, ensuring not to disrupt its proximal blood supply along the cord structures.
- Create a tunnel between the scrotal incision and the penoscrotal junction.
- Deliver the tunica vaginalis flap and cover the entire repair.
- Suture the tunica vaginalis flap in place with interrupted 7-0 Vicryl sutures.
- Place the testicle into the developed subdartos pouch, and pexy it in place with interrupted 4-0 chromic sutures at the 3 o'clock and 9 o'clock positions.

Completion

- Perform glanuloplasty.
- Close in two layers. Use 7-0 PDS to close the deep layer and 7-0 Vicryl to close the superficial layers.
- Mobilize and transpose the mucosal collar flaps ventrally and suture with 7-0 Vicryl sutures.
- Mobilize skin flaps as necessary for skin closure.
- Place a catheter into the bladder for drainage purposes.

■ Buccal Mucosa Graft for Redo Hypospadias Repair

- Unfortunately, not all primary hypospadias repairs are successful. As a result, some patients may require a redo hypospadias repair.
- In instances of a redo hypospadias repair, the urethral plate is often no longer

healthy and requires excision.

- In addition, inner preputial skin is typically not available for redo hypospadias repairs.
- As a result, a hypospadias repair using a buccal mucosa graft is required.
- Harvest a buccal mucosa graft from either cheek or the upper/lower lip.
- Mark out the edges of the desired graft.
- Infiltrate the edges of the graft with 1% lidocaine with epinephrine.
- Harvest the graft using scissors while preserving the underlying fatty tissue (avoid dissecting too deep as this will risk injuring the underlying muscles/nerves).
- Control bleeding from the graft site using bipolar cautery.
- Defat the graft.
- Excise the scarred urethra and surrounding scar tissue to create a healthy vascular bed along the surface of the corporal bodies. Make the buccal graft as wide as possible.
- Tack down the buccal mucosal graft to the location of the urethral plate with 7-0 Vicryl sutures in a quilted fashion.
- Fenestrate the graft with a micro knife to prevent hematoma formation beneath the graft.
- Allow at least 6 months for the buccal graft to mature.
- In a second stage, the buccal mucosa graft is tubularized and the hypospadias repair is completed (**TECH FIG 8**).

TECH FIG 8 • Second stage of proximal hypospadias repair with buccal mucosa. **A.** Healed first-stage repair with buccal mucosa. **B.** Tubularization and closure of

buccal mucosa urethral plate.

PEARLS AND PITFALLS

Indications	■ Proximal and middle hypospadias should be repaired to improve urinary and sexual function. ■ Distal hypospadias typically will not impact overall function but correction can be performed to improve the appearance.
Approach	■ The approach for each hypospadias repair should be dictated by the intraoperative assessment of the chordee and the urethral plate. ■ Counsel the patient and/or parents preoperatively regarding the possibility of needing a staged repair.
Technique	■ Know the limitations of the tissue available for repair. Attempting to do too much in a single stage may result in failure of the repair and increased morbidity for the patient. ■ Use all available tissue to cover the urethral repair to reduce the risk of urethrocutaneous fistula.
Complications	■ If a urethrocutaneous fistula or urethral diverticulum forms, the distal urethra and meatus must be interrogated. If a stricture or meatal stenosis is present, correction of the fistula or diverticulum without addressing the distal obstruction will inevitably lead to recurrence.

POSTOPERATIVE CARE

■ Dressing

- At the conclusion of the surgery, a slightly compressive dressing is typically placed around the penis to reduce swelling and promote hemostasis.
- At our institution, we place a benzoin-soaked Owen gauze around the incisions followed by Coban gauze secured with plastic tape.
- Care should be taken to ensure that the dressing is not too tight as this can decrease blood flow to the glans.
- The dressing is removed by a physician or nurse 4 to 5 days postoperatively.
- After removal of the dressing, a topical antibiotic ointment should be applied to the incisions routinely for 1 to 2 weeks as the incisions continue to heal.

■ Urinary diversion

- As mentioned previously, a urethral stent is sutured in place at the end of the surgery.
- Urinary diversion with a urethral stent allows for proper urethral healing and prevents postoperative urinary retention.
- Some physicians utilize suprapubic tubes for urinary diversion as these may limit bladder spasms. In patients with a history of severe bladder spasms, a suprapubic tube should be considered as strong bladder spasms can expel the urethral catheter.
- The urethral stent is typically removed 1 to 2 weeks postoperatively.
- **Postoperative antibiotics**
 - Historically, postoperative antibiotics were routinely prescribed while the urethral stent was in place.⁹ However, it is currently unclear whether postoperative antibiotics confer a benefit.
 - While awaiting more conclusive studies, we routinely prescribe postoperative antibiotics (ie, Bactrim, Keflex) while the urethral stent is in place.
- **Postoperative evaluation**
 - Take a thorough history of the patient's urinary stream (direction, force, urethral bulging during urination, leakage of urine from along the repair, etc.).
 - Carefully examine the repair and look for evidence of urethrocutaneous fistula (early signs consist of erythema or inflammation along the urethra proximal to the meatus).
 - Examine the meatus for evidence of meatal stenosis.
 - If concern for meatal stenosis or urethral stricture, uroflowmetry can help gauge the strength of the stream.

OUTCOMES

- A successful hypospadias repair should meet the following primary goals:
 - Patent urethra with a good functional urinary stream
 - Intact sexual function (ie, erections, ejaculation)
 - Good appearance
 - Patient satisfaction
- Success of a hypospadias repair is directly correlated with the severity of the hypospadias. Patients with a history of a proximal hypospadias and/or significant chordee requiring a multistaged repair with multiple grafts are more likely to have diminished function or worse appearance.
- Patients with a history of more proximal hypospadias are more likely to have a

shorter phallus, more voiding dysfunction, and lower maximum urinary flow compared to matched controls.¹⁰ Patients are also more likely to report erectile dysfunction and decreased sexual quality of life as adults.¹¹

- However, a study of patient-reported outcomes found that patients with a history of a successful hypospadias repair were more satisfied with the appearance of their phallus and fewer voiding symptoms than compared to patients who had uncorrected hypospadias.¹²

COMPLICATIONS

- Complication rates following hypospadias repair are also directly related to the severity of the hypospadias and the complexity of the repair.¹³
- In expert hands, distal hypospadias using the TIP urethroplasty can be performed with few complications.¹⁴ Most series quote a less than 10% incidence of complications for distal hypospadias repair.
- Short-term complications
 - Glans dehiscence is the most common acute postoperative complication seen following urethroplasty repair and is typically due to closure of the glans under too much tension or by too much ventral pressure from the urethral stent. If the patient has a functional urinary flow and direction, the decision to correct the glans dehiscence typically depends on the patient's or parents' concern for appearance.
 - Hematoma formation and infection are other potential short-term complications.
- Long-term complications
 - Urethrocutaneous fistula formation is the most commonly seen long-term complication and typically presents within 1 year of repair.¹⁵
 - Rates of urethrocutaneous fistula formation with proximal hypospadias repairs have been reported as high as 30% to 50%.^{16,17}
 - The patient or parents typically notices urine leaking from a site proximal to the meatus.
 - Often, there is an associated area of inflammation or wound breakdown.
 - A fistula is unlikely to close on its own with conservative management and reoperation is typically necessary.
 - In general, it is recommended to wait 6 to 12 months prior to reoperation to allow inflammation and edema to resolve.
 - Options for repair include primary closure vs redo urethroplasty.

- For primary closure, the fistula tract is excised and the urethra is closed with multiple layers of well-vascularized tissue. For primary closures, it is essential to calibrate the distal urethra to ensure no obstruction that will increase risk of recurrence.

■ Meatal stenosis

- The rates of meatal stenosis range from 0% to 17%.¹⁸
- Obstruction created by meatal stenosis will increase the risk of urethrocutaneous fistula and urethral diverticula formation.
- At follow-up appointments, it is important to query the patient and/or his family regarding urine stream and to closely examine the meatus.
- If evidence of meatal stenosis, a simple meatotomy performed in the operating room is typically sufficient.

■ Recurrent chordee

- If the patient develops recurrent significant ventral curvature of the penis, the patient may require reoperation if there is concern that it will affect urinary or sexual function in the future.
- For minor recurrent chordee (less than 30 degrees), dorsal plication is usually sufficient.
- For significant chordee (≥ 30 degrees), repeat hypospadias repair may be necessary (although this is uncommon).

■ Urethral diverticulum

- Patients with a urethral diverticulum typically describe a bulging of the ventral aspect of the penis during urination. At completion of urination, compression of the bulge will cause the expulsion of more urine.
- Urethral diverticula typically warrant correct. At the time of repair, excision of the excess urethra is typically sufficient. However, it is crucial to evaluate the distal urethra as there is likely an obstruction, which contributed to the initial diverticulum formation.

■ Urethral stricture

- Patients who present with urethral strictures often complain of a long, slow stream or having to strain to empty their bladder.
- Diagnosis is typically performed by cystourethroscopy.
- For mild, thin strictures, endoscopic management with direct visual incision of the urethra (DVIU) can be attempted; however, in many instances, the stricture will recur.

- For denser strictures or strictures that have failed endoscopic management, reoperation is indicated.

69 Vaginal and Vulvar Reconstruction

CHAPTER

Elizabeth B. Yerkes and Julia Corcoran

DEFINITION

- Neovaginal creation or augmentation of the vaginal canal may be requested in several congenital conditions and in acquired vaginal stenosis. This chapter will address vaginal and vulvar reconstruction in emerging and young adults. It does not include vaginoplasty or labioplasty techniques that may be applied in reconstruction of urogenital sinus in cases of ambiguous genitalia, intersex states, and differences of sex development.
- Vaginal agenesis or congenital vaginal atresia (Mayer-Rokitansky-Küster-Hauser syndrome)
- Vaginal agenesis or insufficiency in the setting of complete androgen insensitivity and intersex/differences of sex development
- Classic bladder exstrophy or cloacal exstrophy
- Vaginal stenosis after early childhood surgery (congenital adrenal hyperplasia, intersex/differences of sex development, or persistent cloaca)
- Secondary changes after pelvic malignancy or graft versus host disease (GVHD)
- Vulvar reconstruction in the form of monsplasty and labioplasty may be requested to align the laterally displaced or offset mons tissue and pubic hair and to reconfigure and stabilize the labia minora after pubertal development in congenital conditions such as exstrophy-epispadias and its covered variants.
- Reduction labioplasty may be requested to address physically bothersome bulk of the labia minora.

ANATOMY

- The paired Müllerian (paramesonephric) bodies fuse in the midline and contact

the urogenital sinus. The sinovaginal bulb is induced and the vaginal plate is formed.

- Müllerian development occurs within first 10 weeks of gestation.
- The labia minora are formed from the urogenital folds and the labia majora and mons from the labioscrotal folds (**FIG 1**).

PATHOGENESIS

- Absent or incomplete development of the Müllerian bodies results in absence or atresia of the female genital tract.
 - Ovaries have a different embryologic development and are spared.
- Failure of the fusion of the Müllerian bodies results in duplication of the vagina or unilateral obstruction or atresia.
- Anomalous descent of the urorectal septum in dividing the cloaca, as in anorectal malformations, may interfere with fusion of the Müllerian bodies.
- Renal development and a portion of skeletal development occur at a similar time to Müllerian development, so anomalies may coexist.
- Pelvic diastasis associated with abdominal wall defects such as bladder exstrophy and cloacal exstrophy also results in nonfusion of the labial and mons tissues. Bifid clitoris also occurs in these conditions.
- Thickening of the labia minora with puberty results in extensive variation in size and shape. Sufficient hypertrophy may occur that some clothing and physical activity are physically bothersome.
 - Hygiene and tissue health may be a concern in young women with limited mobility or ability for self-care.

NATURAL HISTORY

- Vaginal agenesis or atresia does not resolve over time, but maturation of the vulvar tissues and proximal vaginal segment, if present, may facilitate the reconstruction.
- If a uterus and proximal vagina are present, judiciously allowing the vagina to distend with menstrual products may bring it closer to perineum or expand to create more tissue for pull-through reconstruction.
 - Local tissue flaps or nongenital grafts can be used to bridge the distance to the perineum.
 - Surgical benefits of this natural resource must be balanced against pain and the potential for retrograde menstrual flow and peritoneal irritation and deposits that could compromise future fertility.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient age and autonomy as well as family values and motivations will impact discussions about goals and surgical options.
- General discussions may have already involved the parent due to the professional relationship from infancy.
- Once ready to discuss interventions, private discussions with the patient are essential but the parent must also be included for surgical discussions in minors.
- Patient readiness and goals for long-term results must be ascertained.
- Readiness to undertake daily vaginal dilations for indefinite period.
 - Goal may be simply unobstructed menstrual flow or use of tampon.
 - Understanding of need for progressive dilations, and potential additional procedures, thereafter for functional canal
- Readiness or anticipated timeline for intimate sexual contact.

FIG 1 • Sagittal view of pelvic anatomy depicting relationship of urethra, vagina, and rectum in typical development.

- Maturity level to be able to discuss with partner

- Desire for heterosexual penetrative intercourse vs nonpenetrative sexual activities
- Anticipated life events (graduation, prom, marriage) that could be complicated by surgical recovery or complications
- Conflicts between family values/guarantor values and patient's desire for surgery
- Anatomical and patient factors that may inform management
 - Quality of distal UG sinus/vaginal pouch and vulvar skin
 - Presence of functional uterus and proximal vaginal segment
 - Degree of estrogenization and maturation of tissues
 - Location of hair bearing tissues
 - Prior pelvic or genital surgery
 - Prior abdominal, urinary, or rectal surgical procedures
 - Prior chemotherapy or regional radiation therapy in setting of pelvic malignancy
 - Inflammatory bowel disease
 - Dermatologic conditions
 - Continence status for urine and stool
- Patient factors that may impact perioperative care and success
 - Resilience
 - Willingness to ask for and accept support in the perioperative period
 - Compliance
 - Lack of privacy to complete required care (college dorm)
- Timing relative to next expected menstrual period
- History of hypercoagulable state or bleeding diathesis
 - Increased surgical risk in terms of bleeding after deep dissection or from graft donor site
 - Increased risk of perioperative thromboembolic complications after pelvic surgery and prolonged bed rest
- Gastrointestinal or dermatologic conditions
- Continence status for urine and stool

IMAGING

- Imaging is not specifically required for surgical planning, although pelvic ultrasound or MRI is often obtained in the course of establishing certain diagnoses and individual anatomy.

NONOPERATIVE MANAGEMENT

- Daily serial dilation program can achieve a functional vaginal canal in properly selected and motivated candidates.
 - Preferred initial therapy in vaginal agenesis, CAIS, and other intersex/differences of sex development with a vaginal pit or pouch to guide positioning of dilator.
 - May be used to progressively dilate vaginal stenosis.
 - Tissue health and surgical scarring may limit success.
- Assess maturity and commitment to goals of program
 - Program is voluntary and timing should be dictated by patient.
- Ongoing office support is important to verify technique and to enhance success.
- Daily or twice daily dilation for 10 to 20 minutes
 - Goal is to achieve and maintain vaginal depth while increasing caliber.
 - Dilations may cease when consistently sexually active but may otherwise need maintenance dilations.

SURGICAL MANAGEMENT

- Vaginoplasty
 - The individual anatomic situation will dictate whether neovagina construction or augmentation of the caliber of the vaginal canal is required.
 - Skin or mucosal grafts, nongenital pedicled flaps (bowel), and local tissue flaps may be incorporated in the vaginal reconstruction.
 - Choice of donor tissue may be based upon surgeon experience, patient expectations and preferences, donor tissue availability, harvest site morbidity and scarring, and donor tissue properties.
- Monsplasty and labioplasty
 - Inferomedial rotation of mons tissue in bladder exstrophy or cloacal exstrophy
 - Addresses soft tissue asymmetry
 - Allows for concomitant midline abdominal scar revision, with or without umbilicoplasty if desired, and removal of non-hair-bearing midline tissue
 - Melds with labia majora to create greater privacy for the clitoris, labia minora, and vaginal vestibule
 - Supports concomitant revision of asymmetric or mobile labia minora tissue and/or vaginoplasty

- Mobilization of tissue flaps to allow cosmetic and functional coverage of glans clitoris if overexposed after prior feminizing genitoplasty
- Reduction labioplasty
 - Excision or reconfiguration of physically bothersome hypertrophic labia minora

Preoperative Planning

- Review of prior operative notes in individuals with prior pelvic reconstructive procedures.
- A thorough pelvic examination with or without cystoscopy and vaginoscopy is often helpful in surgical planning and patient preparation and counseling.
 - Offer anesthesia or sedation due to the invasive and physically or emotionally uncomfortable nature of the examination.
- Schedule one or more detailed consultations with patient to review all surgical options in the context of individual anatomy and goals.
- Surgical scheduling with consideration of menstrual cycle
 - Avoid menses on day of surgery and for first postoperative week when vaginal stent or mold is used.
 - Continuous menstrual suppression may be considered perioperatively if cycles predictably unpredictable.
- Mechanical bowel preparation in patients with anorectal anomaly and in those who will have bowel vaginoplasty. Enema advised in other vaginal cases.

Positioning

- Sequential compression devices in place prior to positioning
- Position in dorsal lithotomy with all pressure points carefully padded (**FIG 2**).
 - Adequate padding on bed and/or protective barrier on sacral bony prominence, if present
 - Gentle support of atypical lumbosacral anatomy, if present
 - Attention to limited range of motion at hip or lower extremity with some diagnoses
- Standard to low dorsal lithotomy is preferred.
 - Minimizes stress on the spine and nerves in those with pre-existing pathology.

FIG 2 • Dorsal lithotomy positioning. This depicts the highest and widest positioning recommended. Position should accommodate either two surgeons between legs or one surgeon assisting patient's hip. Functional status and hip joint flexibility need to be considered for some diagnoses.

- Acute neurologic change may occur with more exaggerated or prolonged lithotomy.
- Allows participation of cosurgeon from step stool at patient's hip.

TECHNIQUES

■ Augmentation of Caliber of Vaginal Canal: Vaginoplasty and Introitoplasty

- This technique is not neovagina or vaginal replacement but rather augmentation of the existing vaginal canal caliber or circumference (**TECH FIG 1**).
 - Introital, distal, or mid vaginal stenosis
 - Globally narrow but patent vaginal canal
 - Angulation of vaginal canal at introitus
 - Anteriorly positioned and narrow introitus relative to axis of vaginal canal after having undergone exstrophy repair techniques without deep

mobilization of the urogenital complex

- Laterally positioned and angulated introitus in vaginal duplication of cloacal exstrophy

TECH FIG 1 • Narrow vaginal caliber can be augmented with graft techniques. The relationship between the posterior vaginal wall and rectum may be closer than natural relationship in setting of prior reconstruction.

- Remarkably increases vaginal caliber but cannot increase vaginal length due to presence of uterus.
- Relevant to exstrophy where cervix may sit more distally even when well supported.

Enlargement of the Vaginal Canal Caliber

- Radial incisions made at 3:00 and 9:00 with electrocautery (**TECH FIG 2**).
- Lateral location of incisions least likely to injure urethra, bladder base, or rectum.
- Incisions sequentially deepened to expand vaginal caliber without compromising support.

- Desired caliber for penetrative intercourse: two fingers, spread to 2.5 to 3 fingerbreadths.
- For tight stenosis or atresia or with anterior introitus/angulated canal, the authors prefer oral (buccal) mucosa free graft.

TECH FIG 2 • Perineal approach to augmentation procedures. Incisions at 3 and 9 o'clock minimize risk of injury to urethra and rectum, more of a concern in complex anomalies. The incisions are extended cranially into healthy proximal vagina so that even and adequate caliber established.

- For isolated introital stenosis, a local perineal skin flap can be utilized, alone or in combination with free graft, if it does not deform or compromise surrounding anatomy.

Resurfacing With Native Tissues: Buccal Mucosa

- Grafts are harvested from one or both cheeks, depending upon amount of substrate required.
- Graft is defatted and meshed by hand with strokes of scalpel. Alternatively, it may be intermittently temporarily folded and incised with fine scissors (**TECH FIG 3A**).
- Triangular defects will be created bilaterally by the radial incisions.

TECH FIG 3 • **A.** Harvested buccal tissue has been defatted and hand meshed to cover wider defect. For use in bilateral defects, it is divided obliquely into two triangular grafts to advance into defect. **B,C.** Two uses of buccal for augmentation procedures. **B.** Triangular grafts quilted in place bilaterally. Note that native vaginal mucosa remains along posterior wall. **C.** Young adult with deferred repair of urogenital sinus. The vagina was mobilized toward the perineum and spatulated. Buccal mucosa is being inset to bridge to gap and to improve introital caliber. **D.** Vaginal mold carefully inserted. Labia sutured across to prevent expulsion.

- The rectangular meshed buccal graft is cut obliquely into two triangles.
- 4-0 Vicryl suture is preplaced in apex of graft and advanced to apex of the triangular incision.
- The meshed graft is expanded to fill the defect and quilted into the dissected bed with resorbable suture (**TECH FIG 3B,C**). With the introitus and labia at rest, vagina appears normal, not gaping.
- Insert vaginal mold (**TECH FIG 3D**).
- An inflatable vaginal mold with central drainage port is not currently commercially available, but the concept elements are ideally applied to employed substitute.
 - Graft stability without undue pressure on urethra; sterile; impermeable; central drainage port for mucus and blood

■ Neovagina Construction

Perineal Dissection

- Perineal dissection of rectovesical space to create adequate vaginal vault.
- In the expected region of a vaginal opening, there may be a short pouch of supple tissue or flat, firm granular tissue.
- Selection of skin incisions allows the vestibular tissue to be incorporated as local flaps to minimize risk of introital stenosis (**TECH FIG 4**).

TECH FIG 4 • Vaginal agenesis. Incisions avoid infringing upon adjacent anatomy and can preserve tissue to advance into the neovagina. Tissue in this region is not uniformly good quality, however.

- After elevation of flaps and initial electrocautery, the remainder of the dissection occurs bluntly with judicious use of cautery.
 - Care is taken to maintain awareness of urinary tract and rectum during dissection.
- Desired caliber for penetrative intercourse: two fingers, spread to 2.5 to 3 fingerbreadths and at least 8 cm depth. Deep dissection will push peritoneum away but not enter it.

Graft Substrates and Techniques

- After the neovaginal bed has been dissected to allow adequate depth and caliber and a natural axis, the skin or mucosal graft is harvested and prepared.
- Historically, the McIndoe skin graft vaginoplasty was the preferred

approach.

- Harvest classically is a split-thickness graft from the buttocks, although full-thickness grafts have been described.
- Graft is sewn over a vaginal mold with dermal side facing outward. The mold and form are inserted into the neovaginal cavity and held in place for 1 week to allow graft to take.
- Contracture, lack of natural lubrication, and visible harvest site are the primary liabilities.

TECH FIG 5 • Healed buccal mucosa neovagina in case of vaginal agenesis. Note the pliable but not lax introitus and nice match to surrounding tissues.

- Oral (buccal) mucosa free graft is a newer concept for neovagina.
 - It has excellent take and histologic characteristics more similar to vaginal mucosa than skin¹ (**TECH FIG 5**).
 - Neovagina creation and more extensive defects will require maximal harvest from both cheeks.²
 - Graft is inset to line the cavity with interrupted resorbable sutures.
 - Vaginal mold carefully inserted and secured by sutures across labia.
 - Oral care: Chlorhexidine mouthwash and frequent cheek exercises to prevent harvest site contracture during secondary healing.
 - Strict bed rest with log rolling and HOB less than 30 degrees for 6 to 7 days with vaginal mold in place, along with Foley catheter.
- Peritoneal flap neovagina
 - Laparoscopic Davydov procedure³ involves multiple peritoneal flaps

mobilized and pulled through to the perineum to create a neovaginal scaffold.

- Subsequent epithelialization by squamous metaplasia to have vaginal properties.
- Single peritoneal flap modification⁴ involves laparoscopically raising a 10 × 10 cm suprapubic peritoneal flap, leaving an intact pedicle infraumbilically.
 - The flap is pulled through to the perineum and tubularized over a mold.
 - The apex of the neovagina is created laparoscopically with a purse-string suture.
 - The pelvic peritoneum is run closed transversely.
 - Stenting is required continually for 3 months until epithelialized, and then nightly until consistently having penetrative intercourse.

Pedicled Flap Techniques

Sigmoid Colon and Ileum

- Bowel vaginoplasty principles
 - Segment of small or large bowel is harvested on its mesentery and pulled through the dissected rectovesical space for anastomosis at the perineum.
- A 12- to 15-cm segment of sigmoid colon is isolated on a branch of the inferior mesenteric artery via open or laparoscopic abdominal approach. The distal most branches may be ligated to allow more mobility of the mesentery and sigmoid segment⁵ (**TECH FIG 6A**).
- The segment is maintained isoperistaltic. The sigmoid is reconstituted.
- The segment is pulled through to the perineum and secured with interrupted anastomosis of resorbable sutures.
- The apex of the neovagina is oversewn in two layers and fixed to the sacral promontory to minimize prolapse.
- Monti principle
 - Described in small series, with limited follow-up, for sigmoid and ileum.
 - Bowel segment is isolated and opened and retubularized longitudinally.
 - Sigmoid Monti: An 8- to 10-cm segment of ileum is opened near anterior mesentery, such that mesentery forms a cap at apex. This configuration most favorable to allow vagina to reach perineum and to support apex of neovagina⁶ (**TECH FIG 6B,C**).
 - Ileal Monti: 12-cm segment of ileum opened on antimesenteric border.

Two segments may be combined end to end.⁷

TECH FIG 6 • A. Harvest of sigmoid colon for vaginoplasty. Knowledge of vascular supply to colon is essential. Maintaining isoperistaltic orientation may support mucus efflux. Support of the apex minimizes global prolapse, but redundancy may also result in prolapse. **B.** In sigmoid Monti construction, the isolated 8- to 10-cm segment of sigmoid is unfurled to its longest by opening close to the mesenteric border. **C.** The sigmoid is then retubularized in the opposite plane to create the neovagina. The neovagina is then pulled down through the neovaginal bed created via perineal and abdominal dissection.

- Neovagina caliber based upon length of bowel segment harvested. Length of neovagina determined by circumference of bowel segment. Sigmoid has advantage in that regard.
- Advantages over nonreconfigured sigmoid or ileum are the length of

segment required and the more mobile and less obtrusive mesentery.

- Postoperative stenting is recommended with ileal Monti to maintain caliber while the neovaginal cavity heals.⁷ A dilation program then ensues.
- A petroleum jelly gauze roll splint may be left for 24 to 48 hours after sigmoid neovagina. Longer-term stenting is not required with sigmoid neovagina, likely due to bulk of the tissue and natural interior caliber, but dilation of the introitus may be advantageous to prevent stenosis.
- Both segments provide self-lubrication, but the mucus from colonic neovagina may be more problematic in terms of quantity and odor, particularly if redundant segment or introital stenosis.
- Prolapse is uncommon if the bowel segment is designed to limit redundancy and if well supported. Redundant tissue may be excised, and dilations are advisable while healing.
- Diversion colitis related to isolation of the colonic segment from the remainder of the GI tract may result in pain, bleeding, and discharge. Primary gastrointestinal conditions, including malignancy, may also afflict the segment.

Pudendal Thigh (Singapore) Flaps

- This is a fasciocutaneous axial sensate flap based on posterior labial vessels and terminal branches of the pudendal nerve^{8,9} (**TECH FIG 7A,B**).
- Donor area usually has not been involved in previous urogenital and lower abdominal wall reconstructions.
- Donor site closes in a primary manner and hides parallel to the labia majora in the groin/leg sulcus.
- Does not need postoperative stenting or routine dilation.
- Sensation is from the local neural plexus.
- Vagina will be lined with epithelium. Desquamation leads to secretion of sebaceous material. When used to create a total neovagina, lubrication is required for penetrative sexual activity.
- Flap is designed lateral to the labia majora, raised distal to proximal including the deep fascia.
 - Rotation into an expanded vaginal canal or introitus occurs most naturally at the 4 and 8 o'clock positions (rather than 3 and 9 o'clock vaginal incisions) with minimal tension on the point of rotation (**TECH FIG 7C**).
 - Inset with resorbable suture.
 - Close donor in layers, also with resorbable suture material. No need for

drains.

- For total vaginal reconstruction, bilateral flaps can be raised, 15×6 cm, and sewn to each other with epithelial side lining the tube, which becomes the neovaginal canal. The neovagina is then situated into the dissected space between bladder and rectum and suspended well to the most superior point to maintain length and prevent prolapse. Drainage is recommended in this situation.

TECH FIG 7 • A. The fasciocutaneous pudendal thigh flap is based on posterior labial vessels and branches of the pudendal nerve. **B.** The plane of dissection for harvest of the flap, as well as the posterior cutaneous relaxing incision that allows tunneling of the graft. **C.**

Tunneling and union of the paired pudendal thigh flaps in complete vaginal replacement. The flaps must be well anchored to the apex of the prepared neovaginal bed to maintain length and decrease risk of prolapse.

■ Monsplasty and Labioplasty

- Surgeon must determine well in advance of planned procedure whether the mons tissue is adequate for rotational flaps or whether tissue expansion is required.
- Goals:
 - Remove midline shiny hairless skin, revising adjacent midline surgical scar
 - Rotate hair-bearing tissue to midline
 - Create a natural contour of mons and labia majora to allow the clitoris, labia minora and vaginal vestibule to enjoy less overt exposure.
 - Interestingly, the inferomedial rotation to cover the genitalia in females is opposite of the goal in males of evening up the pubic hairline and tissue while visually increasing penile stature through upward rotation of tissues.
- Pubic hair can be clipped but not shaved prior to marking the hair-bearing rotational flaps.
- If vaginoplasty will be performed as well, it will be completed prior to the monsplasty and labioplasty.
- Rotation flaps are marked with relaxing incisions (**TECH FIG 8A**). Midline scar excision and umbilicoplasty incisions are planned as well, if part of the requested procedure.
- The labia minora may require advancement or partial excision for improved cosmesis or patient comfort/hygiene (**TECH FIG 8B**).
 - Planning occurs along with the monsplasty but the actual labial work is easier to visualize prior to recreating the mons.
- A semilunar incision creates a non-hair-bearing skin flap just cranial to the labial complex. This is previously operated tissue (**TECH FIG 8C**).
 - Resultant flap will be turned down to become the underside of the mons-labial confluence and will form part of a hood for clitoral unit.
- The semilunar flap is turned down and rolled to deepen the “hood” or to line the anterior fusion of the labia majora and mons (**TECH FIG 8D**).

- The hair-bearing mons flaps are rotated toward the midline and sutured to each other in layers with resorbable sutures. The inferior or caudal edge of the flaps is sutured to the “hood”/ledge with resorbable suture (**TECH FIG 8E**).
- Expanded flaps require postoperative drains for 4 to 6 days until the flap is well seated.

TECH FIG 8 • The surgical steps are depicted from two different patients. **A.** Exposed urethra and genital tissues to be better concealed with monsplasty. Rotational flaps are marked in preparation for monsplasty. **B.** Advancement of mobile or anteriorly mounded labia minora for improved concealment of clitoris and urethra after childhood repair of exstrophy. **C.** Semilunar incision is raised from previously operated midline hairless tissue. Tissue expanders have been removed and midline closure preplanned with staples. This hairless flap will be turned down to conceal the more intimate anatomy and to line the underside of the monsplasty. **D.** Semilunar flap turned down. Note that the flap has been trimmed in the

midline and closed vertically to conceal the upper labia minora. **E.** Final appearance after monsplasty flaps rotated and approximated. Scar revision, umbilicoplasty and vaginoplasty were also completed in this patient.

■ Reduction Labioplasty

- Goal is to restore comfort rather than to address cosmetic misgivings (**TECH FIG 9**). Reassurance regarding wide spectrum of “normal” is central.
- Defer any intervention until adequate time for adjustments has occurred, as well as development one or more years beyond menses. Potential to “regrow” bulk if development incomplete.
- For whichever is used of the three techniques described below, adhere to the following:
 - Place traction sutures in the tips of the labia minora to gauge tissue to be excised.
 - Mark inner and outer surface of labia minora.
 - Mark both sides for symmetry prior to revising either labia.
 - Perform a two-layer closure.

TECH FIG 9 • Marked, physically bothersome hypertrophy of the labia minora is seen with the labia at rest.

Simple Excision and Closure

- This method offers easiest recovery and least chance to redevelop bulk. There is no potential for flap dehiscence.
 - Greater risk of exposing clitoris or creating irregularity anteriorly, due to more difficulty blending into the naturally folded clitoral hood contour (**TECH FIG 10A**).
- Skin is incised sharply and dartos divided with electrocautery.
- Dartos is run longitudinally with resorbable suture.
- Skin is also closed with continuous resorbable suture.
- Suture line is anterior and may result in more friction during healing but this is not generally symptomatic (**TECH FIG 10B,C**).

Wedge Excision With Advancement

- This method is more prone to postoperative edema and discomfort, more prone to redevelop bulk, and more prone to dehiscence without layered closure.
- Wedge excision and advancement is a full-thickness resection of the central portion of the hypertrophied labia.
- The apex of the flap will advance to the bottom of the wedge incision (**TECH FIG 11A**).
- First layer closure with running resorbable suture begins in corner of wedge incision, gradually anchoring the flap.
- Skin closure is hidden on lateral and medial surfaces of the labia minora. Longer lasting resorbable suture is used on the cutaneous layer at the apex of the flap (**TECH FIG 11B,C**).

TECH FIG 10 • **A.** Retracted labia marked for simple excision. Care must be taken to taper onto the clitoral

hood to avoid cranial irregularity and to avoid exposing glans clitoris. **B.** Labia at rest after simple excision. **C.** Immediate postoperative appearance with labia spread. The anterior suture line is not typically irritating, as it is concealed by the labia majora.

TECH FIG 11 • A. Retracted labia marked for wedge resection and advancement. The running closure of the dartos begins in the apex and progresses down to the tip of the flap. Longer lasting resorbable sutures are recommended at the tip. **B.** Postoperative appearance in a different patient. Note that the suture line is anterior with simple excision but here is hidden in the inner and outer labial surfaces. **C.** The appearance is similar at rest to simple excision.

Hybrid Approach

- Useful in cases in which the labia minora are globally enlarged with posterior insertion.
- Offers benefits of hidden suture line and natural blending with clitoral hood, with a less extensive flap recession than the wedge excision (**TECH FIG 12**).
- Rationale for two-layer closure, regardless of technique:
 - Finlike rather than flat contour of labia
 - Hemostasis, decreased risk of hematoma. Insurance against dehiscence in advancement cases.

TECH FIG 12 • Retracted labia marked for hybrid excision with partial advancement and partial simple closure. Again, the running closure of the dartos begins in the apex and progresses down to the tip of the flap. In this approach, the flap is shorter so the posterior aspect of the closure will be simple two-layer closure.

PEARLS AND PITFALLS

Patient readiness

- Older teens may profess readiness for vaginal reconstruction with immediate goal of ease of tampon use and desire to prepare for future sexual activity, but they may primarily desire to “get it over with.”
- Unless imminently prepared for sexual activity and willing to accept support, they may lack the emotional maturity for the procedure and to adhere to a postoperative dilation program.

Operative preparation

- A strong understanding of pelvic anatomy and potential congenital or postsurgical variations is relevant when dissecting space for neovagina or widening the vaginal canal.
- Injury to the urethra, bladder, or rectum significantly changes the operative experience and potentially long-term functionality.

Hemostasis

- Address vault bleeding with packing rather than blind coagulation in deep cavity.
- Remain alert to adjacent pelvic structures.

Progression of postoperative therapies	■ Even with a highly motivated and mature patient, frequent office visits are recommended early postoperatively. ■ Provider reinforces or redirects patient regarding adequacy of axis and depth of daily use of dilators.
Patient selection for reduction labioplasty	■ Reduction of prominent labia minora for cosmetic purposes is strongly discouraged. ■ Reassure about normal variations in prominence of labia minora in girls and women. ■ For physical bother due to bulky tissue and friction/irritation from clothing: ■ Instruct in trial of manually tucking redundant tissue in after bathing and toileting. ■ Instruct in application of bland ointment nightly to manage irritation. Ointment in daytime may increase bother. ■ Defer surgical management until estrogenization and maturation of tissues is secure. ■ Surprising “regrowth” of tissues may occur if maturation in early evolution.
Labioplasty and perineal care	■ Dehiscence of labial flaps can result in prolonged healing, unfavorable cosmetic result, or asymmetry. ■ Two-layer closure of the labioplasty, particularly at the tip of the labia, reduces risk of separation. ■ Moist perineal environment and oral or topical antibiotic use increase risk of candidal infection and healing concerns. Nystatin powder to groin creases may be protective.

POSTOPERATIVE CARE

- Vaginal packing and vaginal stents/molds
 - Inflatable and solid forms have been utilized. None currently commercially available.
 - Not required for pudendal thigh flaps.
 - Required for approximately 7 days for graft take with skin or oral mucosa.
 - Required all day and night for 3 months in peritoneal flaps due to requirement of squamous metaplasia.
- Mouth care after buccal mucosa harvest
 - Donor site heals by secondary intention and forms fibrinoid plaque within 2 days.
 - Chlorhexidine mouthwash rinses several times daily.

- Mouth exercises minimize likelihood of function-limiting donor contraction. Open wide. Puff check. Mindful manual massage of site by tongue.
- Home dilation program: as described above for each technique. Frequent visits to reinforce technique and improve compliance.
- Activity restrictions
 - Avoid lifting, straddle stance or activity, squatting, or kneeling with perineal pressure for 3 to 4 weeks. Driving restrictions based upon approach.
 - No tampon use or sexual activity until adequate healing determined by surgeon.

OUTCOMES

- A paucity of data exists regarding objective short- and long-term surgical outcomes as well as validated patient-reported outcomes.
- Female Sexual Function Inventory scores compared favorably to controls in large peritoneal flap series.⁴
- Long-term results after sigmoid vaginoplasty report high level of success and patient satisfaction.^{5,10}
 - However, decreased sexual function with abnormal depression indices may occur highlighting importance of pre- and postoperative counseling and support.¹¹
- Tissue quality and match and adequacy of vaginal caliber are very good after buccal mucosa vaginoplasty.^{1,2}
- Sexual activity is allowed by successful maintenance dilations. If pregnancy is achieved, consultation with maternal fetal medicine and caesarean delivery is recommended in neovagina, regardless of type.

COMPLICATIONS

- Injury to surrounding structures: urethra, bladder base/ureter, or rectum may occur with dissection of the neovaginal cavity
- Vaginal contracture or stricture
- Introital stenosis
- Prolapse of pedicled tissues
- Bothersome discharge (sigmoid)
- Secondary changes within donor substrate (eg, chronic inflammation, inflammatory bowel, malignancy)
- Unsatisfactory cosmetic or functional result

CHAPTER Ambiguous Genitalia

Deborah L. Jacobson and Elizabeth B. Yerkes

DEFINITION

- Individuals born with ambiguous genitalia have external genitalia that are not fully typical male or female in appearance. Others have developmental differences that are not externally apparent but may impact future function or well-being. These groups have some degree of discordance between genetic, gonadal, and phenotypic sexual characteristics.
- Medical nomenclature used over the decades was well intentioned but has been viewed as pejorative. Accordingly, nomenclature with multiple subterminologies has evolved with the goal of correcting this situation.
- Hermaphroditism, pseudohermaphroditism, intersex state/disorder, and disorders of sex development (DSD) have been used to describe the state of having ambiguous or nontypical genitalia with or without chromosomal or gonadal anomaly.
- Even the most recent nomenclature, which originated from a consensus of experts, affected individuals, and advocates, is not uniformly accepted by the community. “Disorder” is not widely embraced as a desired description.
- Whereas genital ambiguity and differences of sex development have historically been considered pathologic and in need of surgical correction, contemporary viewpoints acknowledge many phenotypic variations on the continuum of human genital development.
- The authors understand that surgical reconstruction of ambiguous genitalia is a controversial topic and do not presuppose that surgical intervention is necessary for, or would be preferred by, any given individual.
- This chapter will cover the technical aspects of genital reconstruction; however, surgical management should only be undertaken after extensive

counseling and shared decision-making. Longitudinal multidisciplinary care for the individual and family is strongly encouraged.

- This chapter will focus on feminizing genital procedures and the diagnoses that could involve decision-making for these types of procedures.

ANATOMY

■ Clitoris

- The corpora cavernosa (erectile bodies) of the clitoris originate proximally as paired crura, swell medially to form the clitoral bulbs, and unite distally.
- The paired cavernosa support a glans covered by a prepuce of labia minora. MRI imaging studies performed by O'Connell et al demonstrate that the glans lies caudal to the corporal bodies, leading to a natural hairpin curve.¹
- Autonomic input is via the paired cavernous nerves, which originate from the vaginal plexus at the 10 and 2 o'clock positions along the vagina and course dorsally along the proximal urethra.² The nerves travel with the cavernous arteries and enter the clitoral bodies under the pubic arch.
- Somatic supply is via the paired dorsal nerves of the clitoris, which originate from the pudendal nerves, run dorsolaterally along the crura and ischiopubic rami at approximately the 11 and 1 o'clock positions, and enter the glans at the corona. The nerves branch, fanning out along the clitoral bodies dorsally and laterally. Nerves are absent in the dorsal midline and deficient ventrally.
- The cavernous arteries originate from the internal pudendal artery, travel with the cavernous nerves, and enter the clitoral body under the pubic arch. Dissection between the crura at the pubic arch should be avoided.
- Variations from typical clitoral anatomy should be expected in patients with virilization of female genital tissue.

■ Labia

- The labia majora embryologically correspond to the male scrotum. They are separated by the vulvar cleft, which contains the labia minora and clitoris. Together the structures conceal the vestibule.
- The labia minora and urethral plate correspond to the male anterior urethra. The labia join superiorly to frame the glans clitoris as the clitoral hood.

■ Vagina

- The vagina consists of a rugated mucous membrane fixed to a bilayered muscular invagination. It is suspended from the levator ani ventrally, the rectovaginal septum dorsally, and the cervix apically.
- Arterial supply is via uterine, vaginal, and internal pudendal branches

coursing along the anterolateral surface of the vagina.

- Innervation originates anterolaterally via autonomic branches of the uterovaginal plexus and somatic branches of the pudendal nerve.
- The ureters pass adjacent to the lateral margins of the vagina and insert into the base of the urinary bladder.

PATHOGENESIS

- Cloacal development
 - The cloacal membrane folds with differential embryonic growth beginning in week 4, and the cloaca partitioned into anterior (urogenital sinus—UG sinus) and posterior (hindgut) compartments with the descent of the urorectal septum.
 - Disruption of normal cloacal development can lead to persistent cloaca or UG sinus anomalies.
- Development of the external genitalia
 - Fetal androgenization leads to elongation of the genital tubercle, fusion of the urethral folds, and fusion of the labioscrotal folds.
- Development of the abdominal wall
 - Failure of mesodermal ingrowth or premature rupture of the cloacal membrane leads to bladder or cloacal exstrophy.
- Development of the UG sinus
 - Caudal paramesonephric (Müllerian) duct deficiencies may lead to agenesis of the proximal vagina and variable anatomy of the uterus/fallopian tubes (Mayer-Rokitansky-Küster-Hauser syndrome).
 - Lateral paramesonephric (Müllerian) fusion anomalies may lead to uterus didelphys, bicornuate uterus, or unicornuate uterus.
 - Deficiency of the distal UG sinus may lead to vaginal atresia.
 - Incomplete vaginal canalization may lead to an imperforate hymen or transverse vaginal septum.

NATURAL HISTORY

- The natural history of an individual in this population, or the population as a whole, is not entirely known.
- For androgenized individuals, it is unclear what the prenatal hormonal milieu (both in terms of absolute androgen levels and the response of developing genital/nervous tissues) portends for future gender identity or sexuality.
- For virilized females (such as patients with congenital adrenal hyperplasia) in

whom medical control is irregular, continued irreversible changes may occur in the genital tissues.

- The psychosocial outcomes of early vs delayed surgery remain unclear, as does the definition and likelihood of surgical success.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Antenatal course: complications, history of prematurity, and other anomalies
- Evidence of maternal exposure to endogenous or exogenous androgen
 - Severe acne, abnormal hair growth, clitoral enlargement, or Cushingoid appearance
 - Drugs, virilizing tumors, or adrenal disorders
- Family history:
 - Known chromosomal anomalies
 - Fetal/neonatal demise
 - Genital ambiguity or urologic anomalies
 - Infertility or consanguinity
- Physical examination
 - General: overall appearance, dysmorphic features, and general infant well-being
 - Spine: gross deformity or neurocutaneous marks
 - Anomalous findings may indicate genetic syndromes or fetal exposures.
 - Tethered cord or occult spinal cord anomalies are common with select diagnoses.
 - Abdomen: marked distention, hernias, suprapubic masses, and wall abnormalities
 - May indicate bladder outlet obstruction, hydrometrocolpos, or urinary ascites
 - Perineum
 - Labioscrotal folds: prominence, rugation, pigmentation, and presence of gonads
 - Clitorophallic structure: dorsal stretched length, glans width, and corporal consistency
 - Perineal orifices: number, location, and patency
 - Gonads: presence by palpation, location, and consistency
 - Palpable gonadal tissue suggests presence of at least some ipsilateral testicular tissue

IMAGING AND SPECIALIZED EXAMINATION

- Modalities are employed selectively based upon clinical findings and the active differential diagnosis.
- Ultrasonography: Evaluation of the adrenals, kidneys, ureters, bladder, Müllerian structures, and gonads
 - Dilation of genital ducts or duplications or unclear anatomy may lead to additional radiographic or operative investigations.
- Genitography: Delineation of internal genitourinary anatomy
 - A Foley catheter or occlusive nipple is used to occlude the UG sinus orifice.
 - Retrograde administration of contrast material defines the proximal anatomy including sinus length and level of confluence.
 - The vaginal confluence may be missed if the system is not well distended.
- Voiding cystourethrography (VCUG)
 - The catheter may be advanced for VCUG after genitogram if indicated or if the sinus is not opacified. Vesicoureteral reflux and bladder anatomy is assessed during filling, at bladder capacity, during voiding, and after voiding is complete.
 - VCUG alone may not opacify the vagina, so it is less useful study for assessing the UG sinus.
- Endoscopy: Direct visualization of patient anatomy
 - Because general anesthesia is required, endoscopy may be performed at the time of definitive reconstruction unless additional anatomic evaluation is required for surgical decision-making.
- MRI: Delineation of pelvic anatomy and associated spinal anomalies
 - MRI often requires anesthesia in young children and would therefore be considered when other imaging studies are inconclusive.
- Diagnostic laparoscopy: very selectively used in infancy if additional information required
 - Laparoscopy is utilized to clarify internal anatomy and gonadal characteristics.
 - Gonadal biopsy may be necessary in select cases.

DIFFERENTIAL DIAGNOSIS

This list includes only conditions in which patients could potentially be candidates for feminizing procedures.

- Differences in gonadal differentiation

- Pure gonadal dysgenesis
- Mixed gonadal dysgenesis
- Ovotesticular DSD (previously “true hermaphroditism”)
- Differences in androgenization
 - Adrenal sources
 - Congenital adrenal hyperplasia (in 46 XX patients)
 - 21-Hydroxylase deficiency
 - 11 β -Hydroxylase deficiency
 - 3 β -Hydroxysteroid dehydrogenase deficiency
 - 17 β -Hydroxysteroid dehydrogenase deficiency (late virilization in 46 XY phenotypic female)
 - Androgen-secreting tumor
 - Maternal sources
 - Drugs
 - Androgen-secreting tumor
 - Placental sources
 - Placental aromatase deficiency
 - Androgen receptor dysfunction
 - Variations in activity of androgen receptor in various tissues (46 XY patients)
 - Complete androgen insensitivity syndrome (external genitalia phenotypically female, lacking Müllerian structures due to intact MIS)
 - Partial androgen insensitivity (diverse external phenotype, degree of virilization at puberty and innate gender identity not predictable)
- Differences in embryonic development
 - Persistent cloaca
 - Exstrophy-epispadias and cloacal exstrophy
 - Müllerian anomalies
 - Müllerian agenesis (Mayer-Rokitansky-Küster-Hauser syndrome)
 - Vaginal atresia
 - Fusion anomalies
 - Vaginal duplication
 - Uterine duplication
 - Vaginal septum variations

- Urogenital sinus anomalies
 - High vaginal confluence
 - Low vaginal confluence

NONOPERATIVE MANAGEMENT

- Create a multidisciplinary team incorporating experienced pediatric urologists/pediatric surgeons/pediatric gynecologists, endocrinologists, psychiatrists/psychologists, geneticists, and nurses/social support members to work with the parents and child to guide patient care. Consider formal ethics consultations when appropriate.
- There is a broad spectrum of “normal” female external genitalia. Referring providers, parents, and patients may be reassured by education on range of “normal.” Appearance and future functionality are important to consider in the pediatric patient if surgery is requested.
- The timing and indications for feminizing genital reconstruction are currently controversial, and there may be long-term consequences of both action and inaction in this arena.
- Performing feminizing surgery in prepubertal children precludes autonomous self-determination in surgical decision-making and may lead to regret.
- Consider the psychosocial consequences of genital ambiguity, and provide appropriate counseling for patient and parent.
- Patients deserve long-term psychological support, with or without surgical intervention.
- Extended support networks may be found both within the hospital and in the patient’s own community.
- Discuss patient reproductive potential, optimizing patient sexual development and fertility when possible. Administration of androgens or estrogens may be recommended in longer term, depending on the underlying anatomy and function.
- Consider the potential for gonadal malignancy, which varies significantly with gonadal histology and patient pathophysiology. Whenever possible, gonadal preservation should be considered.

SURGICAL MANAGEMENT

Preoperative Planning

- Diagnostic laboratory evaluation may include karyotype, serum electrolytes,

17-hydroxyprogesterone, testosterone, luteinizing hormone, and follicle-stimulating hormone levels. Additional adrenal and sex hormone testing is used more selectively but is essential to make a diagnosis in some cases.

- A thorough examination under anesthesia should be completed, including inspection of external genitalia, palpation for gonads, cystoscopy, vaginoscopy (if applicable), and genitography.
- Consider the need for gonadal biopsy or gonadectomy at the time of intervention, along with possible gonad cryopreservation.
- Patients undergoing vaginoplasty require bowel preparation (enema vs polyethylene glycol solution) prior to surgical intervention.

Positioning

- Isolated genitoplasty with or without repair of a low UG sinus is generally performed in frog-leg (infants, young children) or dorsal lithotomy (older patients) position with padding of all pressure points.
- For reconstruction of a high UG sinus, most patients will require both prone and supine positioning, so total lower body preparation is utilized. This preparation may be advantageous in infants and young children for sterility of the field, whether high or low confluence.
- Ensure there are no IVs in lower extremities.
- A single-shot caudal block is reasonable in eligible patients, but a continuous caudal catheter is not utilized intraoperatively.
- After endoscopy and catheter placement, keep the catheters sterile and move the patient up the table for second prep. Prep the lower body circumferentially from the xiphoid to the toes.
- Place feet and legs in a stockinette.
- Drape to allow for lower body repositioning from supine to prone within the drape (**FIG 1**).
- Position the patient with stacked towels under the pelvis. Initial prone vs supine positioning will depend upon the planned procedures.

Approach

- Primary components of the feminizing genitoplasty include the following:
 - Clitoral degloving
 - Elevation of the urethral plate and mobilization of the common UG sinus
 - Clitoral reduction
 - Urogenital sinus reconstruction and vaginoplasty

- Creation of a clitoral hood and labioplasty

FIG 1 • Prone view of circumferential body preparation from the xyphoid to the toes. The child is toweled out and “passed through” a drape to allow transitions from supine to prone within the drape. The hips will be elevated on stacked towels.

- Several clitoral reduction techniques are utilized in contemporary feminizing genitoplasty.
 - Each is performed with attention to clitoral nerve sparing.
- The timing of reconstruction elements is controversial.
 - “Early” single-stage reconstruction of the genitalia and UG sinus is performed with the goal of no additional procedures and no memory of the recovery. Additionally, the excess UG sinus tissue and genital skin can be redistributed as needed if the procedure is completed in a single stage. Despite these potential advantages, the smaller caliber of the infant vagina may increase the risk of vaginal stenosis and the likelihood of secondary procedures. Routine postoperative vaginal dilations are not recommended in this age group.
 - “Late” reconstruction preserves autonomous self-determination and allows the full advantage of virgin planes and tissues.
 - There may be limited options for positioning older patients.
 - Vaginal dilations will be required postoperatively, whether by medical grade dilators or sexual activity, so emotional maturity and commitment to outcomes are essential.

- A staged reconstruction, by deferring either genitoplasty or vaginoplasty, precommits to two operative events and limits the redistribution of healthy tissues. The second stage may involve previously operated tissues.
- The operative approach varies based on:
 - The surgical components to be included
 - The level of vaginal confluence in the UG sinus (“high” vs “low”)
 - The degree of virilization

TECHNIQUES

■ Feminizing Genitoplasty: Examination

- If repair of the UG sinus (urethroplasty and vaginoplasty) will occur:
 - Examination under anesthesia and endoscopy is performed in the dorsal lithotomy position to define UG sinus anatomy and denote the relative positions of the urethra and vagina.
 - A Fogarty catheter is inserted into the vagina and clamped. A Foley catheter is inserted into the bladder and periodically drained.
 - Alternatively, a Councill tip Foley catheter may be introduced into the vagina over a wire after emptying the bladder. Once the confluence of urethra and vagina is identified surgically, the catheter is redirected to the bladder.
 - A sponge may be placed into the rectum to allow for intraoperative palpation of the anterior rectal wall.
- If repair of the UG sinus will *not* occur:
 - Examination under anesthesia is performed.
 - A Foley catheter is inserted into the bladder and periodically drained.

■ Contemporary Nerve Sparing Clitoral Degloving

- Blunt lysis of adhesions between the glans clitoris and inner prepuce is performed.
- A retraction suture is placed through the dorsal midline of the glans (**TECH FIG 1A**).
- The skin is retracted to expose the inner prepuce. A dorsal degloving

incision is made more proximally than a standard circumcising incision to preserve preputial tissue for glans coverage as the inner layer of the clitoral hood (**TECH FIG 1B**).

- Placement of the ventral degloving incision varies with the degree of virilization and intended procedure.
 - When the UG sinus meatus is found on the glans clitoris, the ventral degloving incision is immediately beneath the corona.
 - When the UG sinus meatus is located proximal to the glans clitoris, the ventral degloving incision begins immediately proximal to the orifice and extends distally to flank the urethral plate (**TECH FIG 1C**).
- The clitoris is sharply degloved to the base, preserving the dartos with the skin and leaving Buck fascia and the underlying neurovascular bundle undisturbed (**TECH FIG 1D**).
 - The suspensory ligament will be encountered dorsally and should be left in situ proximally to support the proximal clitoral body and the glans after clitoral reduction.

TECH FIG 1 • A. A traction suture placed through the dorsum of the glans clitoris facilitates visualization of the urethral plate. **B.** The clitoral degloving incision is more proximal than is typical for circumcision to allow for creation of the inner layer of a clitoral hood. The *blue line* delineates the typical circumcising incision, and the *green line* delineates the preferred degloving incision. **C.** When the urethra is proximal, the ventral degloving incision flanks the urethral plate. A posteriorly based omega-shaped perineal flap is created on the perineum at the time of the dorsal and ventral degloving incisions. The labia majora will ultimately be moved posteriorly to flank the perineal flap after it has been advanced into the vagina. “P” denotes a posteriorly based flap and “L” denotes the labia majora. **D.** Preservation of the paired dorsal neurovascular bundles beneath Buck fascia. “I” represents the inner prepuce, which becomes the inner layer of the clitoral hood. The dorsal overlaid lines represent the neurovascular tissue.

■ Elevation of the Urethral Plate and Mobilization of the Common UG Sinus

- Terminology: If the orifice of the UG sinus is on the clitoral body, a “urethral plate” consisting of a mucosal strip and its underlying spongiosum extends along the ventral clitoral body from the UG sinus orifice to the glans. “UG sinus” refers to the intact common channel.
- The urethral plate/common UG sinus is elevated off the ventrum of the clitoral body, leaving the tunica albuginea intact.
- The point of distal division varies based on the degree of virilization and whether reconstruction of the UG sinus is planned.
 - If UG sinus reconstruction is planned, the urethral plate or common UG

sinus is divided along the distal clitoral body and fully mobilized (**TECH FIG 2**). If the UG sinus orifice is in the glans, the UG sinus is transected distally rather than dissected out of the glans.

TECH FIG 2 • The prepuce is fully mobilized away from the clitoral body. Note that the inner layer of the clitoral hood is partially covering the glans in this photograph. The UG sinus is also mobilized. A catheter is in place, and multiple traction sutures assist with mobilization.

- If UG sinus reconstruction is deferred, the urethral plate is elevated and ultimately partially resected to allow recession of the glans.

■ Clitoral Reduction

- Historical feminizing genitoplasty procedures included clitorrectomy and clitoral recession procedures, each of which resulted in dysfunction. Contemporary approaches emphasize both cosmesis and function. The dorsal neurovascular tissue is preserved in each approach.
- Conservation of clitoral tissue and its neural innervation is of paramount importance for the preservation of genital sensitivity.³
- Two main techniques allow debulking of the hypertrophied corpora cavernosa with preservation of the glans clitoris on its neurovascular pedicle.
- In both techniques, Buck fascia is incised ventrally, exposing the tunica albuginea.

- In the description coined nerve-sparing ventral clitoroplasty (NSVC),³ the dorsal neurovascular bundle is elevated off the tunica albuginea along the length of the clitoral body and left in continuity with the glans (**TECH FIG 3A**). Use of papaverine minimizes vascular spasm that may compromise the glans clitoris.
 - The erectile bodies are dismembered from the glans and transected 1.5 to 2 cm from the bifurcation.
 - The tunica albuginea is oversewn to allow for clitoral erection.
 - The glans is resected with care to avoid kinking of the neurovascular bundle.
 - Glans support and proximal engorgement are afforded.
- The alternative nerve-sparing approach, as preferred by the authors, differs in that the dorsal tunica albuginea is preserved along with the neurovascular bundle (**TECH FIG 3B**).
 - The intact tunica albuginea protects the neurovascular tissue without adding problematic bulk.
 - Parallel incisions are created along the ventrum of the clitoral body and the erectile tissue.
 - The erectile tissue is bluntly dissected and ligated proximally, preserving the shell of tunica albuginea dorsally and laterally.
 - The glans is approximated to the corporal stump. The intact dorsal tissue gently bows into the subcutaneous tissue⁴ (**TECH FIG 3C**).
- Corporal-sparing clitoroplasty has been proposed as a means of preserving the corporal bodies to allow for potential reversal of feminizing procedures and phalloplasty in the future.⁵
 - After the clitoris is degloved, the glans and neurovascular tissue are elevated off the clitoral body as a unit.
 - The plane between the corpora is sharply dissected, allowing separation of the hemicorpora.
 - The tunica albuginea of each hemicorpora is oversewn with absorbable sutures to create independent bodies.
 - The hemicorpora are now rotated inferolaterally into dartos pouches fashioned within the labia majora.
- The glans clitoris is rarely reduced in size. Concealment can be accomplished without glans reduction.
- If reduction is deemed necessary, wedge resection from the ventrum is

avored. Innervation is denser dorsally.⁶

TECH FIG 3 • A. Buck fascia and the neurovascular tissue are mobilized off the clitoral bodies and preserved. Full-thickness resection of the clitoral bodies is performed. **B.** Dissection proceeds ventrally into the corpora. Spongy erectile tissue is excised and ligated proximally, but the shell of tunica albuginea and the neurovascular tissue are both preserved. **C.** Sagittal view of the glans clitoris seated on debulked clitoral bodies. Note that the neurovascular tissue is preserved and not kinked.

■ Urogenital Sinus Reconstruction and Vaginoplasty

Creation of a Perineal Flap

- If UG sinus mobilization is planned for urethroplasty and vaginoplasty, a posteriorly based omega-shaped perineal flap is created on the perineum at the time of the dorsal and ventral degloving incisions (see **TECH FIG 1C**).
- Raising a perineal flap exposes the bulbar portion of the UG sinus and allows dissection between the UG sinus and rectum.
- The flap will ultimately be advanced into the vagina to increase the distal vaginal caliber. Advancing the flap reduces the risk of stenosis.
- Flap vaginoplasty without partial mobilization of the UG sinus enlarges the UG sinus, but the urethral meatus remains recessed, or hypospadiac.
- Overzealous advancement of the perineal flap may result in dehiscence, ischemia, or an unnatural slope of the perineal body. Additionally, this tissue will typically be hair-bearing and lacks mucosal properties.

Total and Partial Urogenital Mobilization (TUM and PUM) (**TECH FIG 4A**)

- Mobilization of the common UG sinus brings the genitourinary complex toward the perineum,^{7,8} facilitating either flap vaginoplasty or pull-through vaginoplasty.
- Multiple stay sutures are placed around the common UG sinus orifice to facilitate a traumatic retraction. The common UG sinus is dissected as a unit proximally, including partial dissection under the pubis (**TECH FIG 4B**).

TECH FIG 4 • Urogenital mobilization, sagittal view. A posteriorly based perineal flap (*P*) has been mobilized to facilitate posterior exposure and for incorporation to vagina, if needed. **A.** In total urogenital mobilization (TUM), the UG sinus is mobilized as a unit both between the vagina and rectum and anteriorly under the pubis. The supportive pubourethral ligament (*black arrow*) are taken down for this extensive mobilization. In partial urogenital mobilization (PUM), the anterior dissection stops short of dividing the pubourethral ligaments. **B.** A catheter is in place in the UG sinus and multiple traction sutures facilitate dissection. **C.** The vagina has reached the perineum and is spatulated posteriorly to allow advancement of a perineal flap.

- The posterior perineal attachments are sharply divided, dropping the rectum away from the bulbar section of the UG sinus. As posterior dissection continues, the peritoneum is bluntly pushed away from the posterior wall of the UG sinus.
- If this degree of anterior and posterior mobilization is not sufficient to access the confluence, additional dissection occurs anteriorly, dividing the

pubourethral ligament. This step differentiates PUM from TUM.⁸ TUM bears the potential risk of disturbing pelvic support and continence mechanisms.

- The sinus is further mobilized toward the perineum, and the vaginal balloon catheter is palpated.
- If the confluence is still high, the patient is placed prone and the vagina is separated from the common UG sinus.
 - The common UG sinus is opened over the distal vagina near the confluence, where the vagina is relatively underdeveloped. The posterior wall incision can be extended proximally and distally until the urethral meatus is seen. If a Councill tip Foley was placed into the vagina, the catheter is redirected up the urethra into the bladder.
 - Meticulous sharp dissection creates a plane between the anterior wall of the vagina and the urethra and bladder base. Multiple traction sutures are placed on the vagina (**TECH FIG 4C**).
 - Following adequate vaginal mobilization, the common UG sinus becomes the urethra with a running closure of absorbable suture over the Foley catheter.

Use of the Excess Mobilized Common UG Sinus

- Best use determined by the distance for the vagina to reach the perineum.

TECH FIG 5 • The mobilized UG sinus may be opened anteriorly (**A**) so that the excess sinus may be incorporated into the vagina. Patient A had an ASTRA. If the sinus is opened posteriorly (**B**), the excess sinus creates a mucosa-lined vestibule. Patient B had partial

urogenital mobilization. Note the open sinus (S), the frondular hymenlike tissue at the vaginal opening (V) and the posteriorly based perineal flap. The vagina will be spatulated further posteriorly to reach normal caliber. The flap will be advanced to complete the posterior wall of vagina.

- If the vagina remains high, the urogenital sinus can be used to complete the vaginal wall.
 - The common UG sinus can be incised anteriorly and the tissue is everted and advanced to become the anterior vaginal wall as a Passerini-type flap⁹ (**TECH FIG 5A**).
 - The excess UG sinus tissue can be used in a variety of ways to augment the vagina.^{9,10}
 - The patient is then turned supine and the perineal flap is advanced posteriorly if needed.
- If the vagina has reached the perineum, the patient is turned supine.
 - The common UG sinus is incised posteriorly, and the redundant sinus tissue is used to line the vaginal vestibule (**TECH FIG 5B**).
 - The posterior vaginal wall is spatulated to accept the perineal flap.
- Labioplasty is completed.

Comparison of Surgical Options for Vaginoplasty Based on Level of Confluence

Low Vaginal Confluence (**TECH FIG 6**)

- If a low vaginal confluence is present, partial urogenital mobilization (PUM) is completed (see above).
- The mobilized sinus is opened posteriorly to expose the urethra and vagina.

TECH FIG 6 • Completion of vaginoplasty after PUM. Note separate urethral (U) and vaginal (V) openings. The posteriorly based perineal flap (*asterisk*) allows a wider vaginal caliber. Silk traction sutures are holding the excess UG sinus, which will line the vestibule with a robust mucosa. The labia majora will be advanced posteriorly to flank the perineal flap.

- The vagina is incised posteriorly to increase the caliber, and the perineal flap is advanced into the vagina with interrupted absorbable sutures.
- Labioplasty is completed.

High Vaginal Confluence

- If a high vaginal confluence is present, prone positioning will optimize visualization for a vaginal pull-through procedure.
- Either a classic pull-through or TUM with pull-through may be used.
 - In the classic pull-through, the UG sinus is not mobilized. It is opened posteriorly in the midline, extending the incision into the normal-caliber vagina. The vagina is dissected off the urethra or bladder base and mobilized toward the perineum.
 - In TUM, the UG sinus has been fully mobilized (see above), and if the vagina has not reached the perineum, the UG sinus is opened over the confluence to expose the vaginal lumen and proximal urethra. Keeping the UG sinus tissue intact allows more flexibility for use of excess tissue.^{9,10}
- Stay sutures are placed along the incised margin of the vagina to facilitate retraction.

- A malleable retractor is placed and elevated toward the rectum to optimize exposure.
- The investing structures are dissected off the vagina along the posterior and lateral walls.
- Once the posterior wall is exposed, the retractor is placed in the vaginal lumen to facilitate exposure of the junction of the vagina with the common UG sinus.
- The mucosa of the anterior vagina is incised transversely and additional traction sutures are placed.
- The anterior plane is dissected sharply; it is very thin distally and care must be taken to avoid entering the urethra or urinary bladder. Dissection continues anteriorly and posteriorly until the vagina can reach the perineum with or without local flaps.
- Following adequate vaginal mobilization, the common UG sinus is reconstituted as the urethra via multilayer closure over the Foley catheter.
- Regional flaps can be mobilized to help the vagina reach the perineum.
 - If TUM was employed, the excess common UG sinus may be incised anteriorly to allow eversion of the flap and incorporation as the anterior vaginal wall (Passerini-type flap).
 - The patient is rotated supine and the perineal flap is affixed to the vagina with interrupted absorbable sutures.
- One can imagine how the advantages provided by alternating between the posterior prone approach and the supine anterior view are unrealistic in teens and adults. Even if the urogenital sinus work can be completed prone, clitoroplasty and labioplasty should only be attempted supine or in lithotomy.

Anterior Sagittal Transrectal Approach

- Anterior sagittal transrectal approach (ASTRA) is a newer alternative approach for pull-through vaginoplasty in the setting of a high confluence.¹¹
- Aside from the transrectal exposure of the UG sinus, the dissection of the vagina off the common UG sinus and subsequent urethroplasty is similar to a TUM.

TECH FIG 7 • Comparison of the approach to the vagina for urogenital mobilization (perineal; **A**) vs ASTRA (transanorectal; **B**).

- Exposure of the posterior wall of the vagina is afforded by a full-thickness sagittal incision of the anterior wall of the anus and rectum; the surgeon's view and the access to the vagina are thereby more direct. There is a tradeoff between this enhanced exposure and the potential morbidity of opening the rectum. The procedure can be safely completed without colostomy, but some opine that this additional risk is not justified (**TECH FIG 7**).
- Suitability for the ASTRA approach is determined at the time catheter placement by transrectal palpation of the vaginal catheter balloon (greater than 3 cm from the anus).
- Perioperative preparation includes the following:
 - Preoperative mechanical bowel preparation.
 - Triple antibiotic therapy or equivalent for 72 hours.
 - Diet held until evidence of bowel function.
- The procedure begins in prone position, and the rectum is opened (**TECH FIG 8A**).
- Clitoroplasty and dissection of the distal UG sinus are deferred.
- Without otherwise mobilizing the UG sinus first, the vagina is opened posteriorly (**TECH FIG 8B**) and dissected off the common UG sinus, similar to that described for TUM, and the UG sinus is closed as the urethra.

TECH FIG 8 • A. Full-thickness incision of the anterior anus and rectal wall. Nasal speculum in rectum. **B.** UG sinus opened to expose vaginal catheter. Catheter will be redirected to urethra. **C.** Skin is being incised in the midline toward the UG sinus meatus. Note that there is no midline posteriorly based perineal flap.

- The perineal skin is then incised to the level of the UG sinus orifice, and the posterior wall of the UG sinus is dissected (**TECH FIG 8C**).
- The procedure otherwise differs from TUM in that the anterior wall of the UG sinus is only mobilized under the pubis if additional sinus tissue will be needed to complete the vaginal wall.
- Otherwise the posterior wall of the sinus is opened, exposing healthy mucosa to line the vestibule.
- The rectum is closed and the anterior sphincter complex is reconstituted. The perineal body is closed in layers and sutured directly to the spatulated posterior vaginal wall.
- The patient is rotated prone for clitoroplasty and labioplasty.
- Because the cutaneous incision extends from anus to common UG sinus orifice, there is no midline posteriorly based flap.
 - This has not generally been required, but a flap could be raised from each side if necessary.
 - In either case, closure of the deep perineal tissues and a two-layer skin closure are recommended.

■ Creation of a Clitoral Hood and Labioplasty

- The remaining dorsal clitoral skin is incised in the midline to approximately 1.5 cm from the base, creating the Byars flaps that will be fashioned into the

clitoral hood and labia minora (**TECH FIG 9A**).

- The intact 1.5 cm of clitoral skin is plicated with interrupted absorbable dermal sutures to provide contour to the clitoral hood.
- This outer layer of the clitoral hood is sutured to the inner layer of the hood reserved at the time of initial clitoral degloving.
- The paired Byars flaps are tapered and tucked next to the urethral plate, creating a fin of tissue similar to labia minora. The medial border of each flap is sutured to the urethral plate or mucosa-lined vestibule with interrupted absorbable sutures.

TECH FIG 9 • A. Fashioning clitoral hood and labia minora from clitoral skin. The clitoral skin is incised to create Byars flaps (*black line*). The incision stops about 1.5 cm short of the base to create the outer hood. Note that the initial clitoral skin incision allowed sufficient skin to form the inner layer of the hood (*black arrow*). **B.** Byars flaps are draped around the glans clitoris as the clitoral hood and labia minora.

Dermal sutures provide contour to the outer layer of the clitoral hood. The labia minora are trimmed (*dotted lines*) for labial configuration and sutured to vestibular tissue. Dog ears of clitoral body skin are trimmed anteriorly to allow provide a grooved contour between the labia minora and majora. Two-layer closure of the inferior apices will minimize the risk of labial dehiscence. **C.** Completion of labioplasty after clitoral reduction and vaginoplasty with a posteriorly based perineal flap. Full-thickness debulking at the apices of the labia majora may be undertaken to reduce the loose skin folds. Rugation will persist to some degree. The labia majora are advanced posteriorly to flank the perineal flap, with a two-layer closure at the apices.

- If UG sinus reconstruction with vaginoplasty has been completed, the labia majora will also be addressed (**TECH FIG 9B,C**).
 - If the labia majora are anteriorly positioned, they are mobilized and advanced posteriorly to flank the perineal flap (if used).
 - Full-thickness debulking at the apex may improve appearance, although rugations of the androgenized tissue may persist. Care should be taken with fibrofatty debulking, as this may result in devascularization or asymmetry.
- A cleft is preserved between the labia minora and the labia majora by excising a dog-ear of skin anteriorly. Closure is via interrupted absorbable sutures.
- A two-layer closure at the apex of each labium will minimize the risk of dehiscence.

PEARLS AND PITFALLS

Preoperative decision-making

- Multidisciplinary guidance is essential prior to performing irreversible genital surgery, and operative interventions should only be undertaken after extensive counseling.

	■ The impact of deferring intervention until the age of consent is not fully understood.
Positioning	■ Coordinate with the anesthesia team to ensure upper body IV access, avoidance of continuous caudal catheterization in setting of total lower body preparation, and communication regarding multiple anticipated position changes. ■ Create a broad sterile field with total lower body preparation and strategic use of surgical drapes to facilitate genitoplasty and UG sinus reconstruction in younger children. ■ Adolescents and young adults should be placed in dorsal lithotomy position. The exposure for high dorsal dissection is much more limited in this population.
Labioplasty	■ Two-layer closure of the apices of Byars and labia majora flaps will minimize the risk of labial dehiscence as postoperative edema ensues.
Inadequate surgical preparation	■ Inadequate familiarity with patient anatomy can lead to rectal injury during posterior dissection of the UG sinus or can lead to neurovascular injuries of the clitoris and urinary tract. ■ A collaborative mentality is strongly recommended when complex anatomy may place patients beyond an individual surgeon's expertise.

POSTOPERATIVE CARE

- A Penrose drain is placed in the vagina after vaginoplasty and removed in 24 to 48 hours.
- An indwelling urethral catheter is left to drainage for several days postoperatively. Catheters may be left in place for up to 2 weeks depending on the nature of the UGS, the degree of urethral reconstruction, or other patient factors.
 - Care should be taken to secure the catheter so it does not compromise the integrity of the labial flaps.
- Ointment and bulky fluff compression dressings are applied to the perineum and left in place for 2 or 3 days. Dressings are removed prior to discharge.
- Perineal mobility is minimized in the early postoperative period.
 - In infants, a mermaid wrap around the knees is appropriate. Foam or a thick gauze roll between knees and ankles prevents pressure damage.
 - Older individuals should be instructed to avoid straddling, squatting, kneeling, or Valsalva to minimize perineal engorgement.

- Short-duration, plain water tub soaks are begun approximately 3 days postoperatively, except in ASTRA.
- Bacitracin ointment is applied to the perineum for 3 days postoperatively, after which use of bland ointment is recommended.
- Care is taken to avoid moisture trapping beneath the ointment with consequent skin maceration or dehiscence.

OUTCOMES

- Historic outcomes evaluations revealed substantial patient dissatisfaction with genital appearance and the need for repeated surgical intervention.^{12,13}
- Creation of an adult-caliber vaginal introitus in infancy is neither feasible nor desired.
- Under ideal circumstances, creation of a supple introitus during infant vaginoplasty will allow for passive or active vaginal dilations at the age of sexual maturity. There is a reasonable probability of introital revision, and this should be emphasized in preoperative counseling.
- Retrospective cohort studies have described impairment in clitoral sensitivity among patients undergoing feminizing genitoplasty^{13,14} and demonstrated a linear correlation between diminished sensation and sexual dysfunction.¹⁵
- As surgical technique has improved, prospective cohort studies reveal more favorable cosmetic outcomes following feminizing genital surgery^{5,16,17} (**FIG 2**).
- Retrospective evaluation of clitoral sensation and perfusion reveals improvement in functional outcomes following nerve-sparing clitoroplasty¹⁸; however, prospective assessments of clitoral sensation and overall sexual function are lacking.
- Further prospective studies are also needed to assess surgical and psychosocial outcomes among this population.
- If surgery is done during infancy, there is a significant lag time between surgery and sexual maturity. Educated modifications in technique are therefore challenging.

FIG 2 • Immediate postoperative result after a pull-through vaginoplasty via ASTRA in a child with completely fused labia majora and a high UG sinus. Creation of clitoral hood includes contouring dermal plication sutures. The labia majora did not require posterior mobilization in this child. Due to the ASTRA approach, there are perineal body sutures rather than a posteriorly based perineal flap.

COMPLICATIONS

- Clitoral ischemia with loss of tissue
- Dehiscence
- Vaginal stenosis
- Diminished clitoral sensation, impaired sexual function
- Unsatisfactory cosmetic outcome
- Patient regret

Section XIX: Emergency Department Lacerations

Facial Laceration Emergency Room Closure Techniques

71
CHAPTER

Christina Pasick and Peter J. Taub

DEFINITION

- Facial soft tissue injuries are commonly encountered in the emergency room. Common etiologies are motor vehicle collisions, animal bites, sports and job-related injuries, and interpersonal violence.
- These injuries are often complex and may have significant impact on the patient's facial form and function.
- Plastic surgeons are often consulted by the emergency room physician or requested by the patients themselves for facial injuries ranging from simple lacerations to complex craniofacial trauma.

ANATOMY

- Facial aesthetic subunits should be considered when planning reconstruction so that incisions lie within or along the border of the involved subunit (**FIG 1**).
- Lacerations deep to the superficial musculoaponeurotic system (SMAS) risk injury to the facial nerve branches. See Table 1 for physical exam findings in injured facial nerve branches.
- Blunt injuries to the face may cause a temporary neuropraxia to the nerve that does not require immediate operative measures but instead should be observed for 3 weeks.

FIG 1 • The facial aesthetic subunits. Scars are more inconspicuous when planned within or along these lines.

- Extensive branching and cross-innervation of the branches of the facial nerve is present medial to the lateral canthus (**FIG 2**). As a general rule, lacerations of the nerve medial to the lateral canthus do not require repair. However, lacerations to the marginal mandibular nerve medial to the lateral canthus of the eye should be repaired, as there is not adequate crossover for functional recovery of the depressor muscles following medial injury to the marginal mandibular nerve. The temporal branch is another facial nerve branch with minimal crossover, but this nerve will most likely have innervated its target muscles (frontalis) should a laceration occur medial to the lateral canthus.
- The sensory nerves of the face can be utilized as guidelines for local anesthesia nerve blocks. Suspicion for nerve laceration should be elevated

when lacerations are present in these regions.

- Knowledge of the location of the major arteries of the face can raise suspicion for lacerated vessels in deep wounds in these locations (**FIG 3**).
- The parotid duct or Stensen duct lies in the line drawn between the tragus and the middle of the upper lip. Stensen duct empties into the mouth at the buccal mucosa overlying the second maxillary molar.

PATHOGENESIS

- The mechanism of injury (ie, motor vehicle collision) can help to gauge the force involved in creating the injury and help determine if additional radiographic studies are necessary.
 - Suspect a larger area of tissue injury when dealing with a crush wound as opposed to a simple laceration.
- Human bites should all be treated as contaminated wounds, and the need for careful irrigation and prophylactic antibiotics apply.

Table 1 The Physical Exam Findings Behind Injuries of the Facial Nerve Branches

Facial Nerve Branch Injured	Weakness Observed on Physical Exam
Temporal branch	Inability to elevate eyebrow
Zygomatic branch	Inability to close eye
Buccal branch	Inability to elevate upper lip
Marginal mandibular branch	Inability to evert lower lip
Cervical branch	Inability to activate platysma

FIG 2 • The branches of the facial nerve: temporal, zygomatic, buccal, marginal mandibular, cervical. Extensive branching and cross-innervation is present medial to the lateral canthus (*marked line*). As a rule, lacerations of the nerve medial to the lateral canthus do not require repair.

- Organisms often found in human mouths include *Eikenella*, *Staphylococcus*, *Streptococcus viridans*, and *Bacteriodes*.¹
- If the initial injury is not treated and the patient presents with a developed infection, inpatient therapy with IV antibiotics is often warranted, with a low threshold for OR debridement and washout.
- Dog bites are the most common type of animal bite in the emergency room and are often contaminated with various bacteria, including *Pasteurella multocida*, *Bacteroides*, *S viridans*, and *Capnocytophaga*.¹

- Infection rates are not as high as seen in cat bites due to lower bacterial levels and the open avulsion-type injury seen in dog attacks rather than the deep puncture injury in cat bites that can trap bacteria. These open wounds facilitate irrigation.
- Crush component of dog bites often results in substance loss and requires debridement and reconstruction of avulsed tissue.²
- High incidence in the pediatric population.³
- Cat bites should always be considered heavily contaminated wounds, as the nature of the long and narrow cat teeth lead to deeply penetrating wounds with a very narrow orifice, resulting in seeding of bacteria into deep structures.
- Organisms often found include *Pasteurella multocida* and *Bartonella henselae*.

FIG 3 • The major arteries of the face. These arteries arise from the external carotid system (in red) and the

internal carotid system (in *green*). Path of the parotid duct or Stensen duct. Lacerations in this line should be evaluated for laceration of the parotid duct system.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Trauma patients require a primary trauma survey and secondary trauma evaluation immediately.
- The patient should be assessed for more serious intracranial, ophthalmologic, and cervical spine injuries.
- Suspect skull base fracture with the following signs: raccoon eyes (periorbital ecchymosis), battle sign (postauricular ecchymosis), otorrhea, or hemotympanum.
- Take a complete history.
 - The etiology and timing of the wound
 - Other medical problems that may put the patient at risk for wound healing difficulties
 - Medications that may make the patient a bleeding risk
 - Smoking status
 - Tetanus vaccination history
- Physical examination
 - Remove all clothing, jewelry, dried blood, and foreign material that may obscure the examination.
 - Use a systematic approach, inspecting for lacerations, avulsions, “road rash,” and areas of edema or ecchymosis.
 - Palpate wounds for bony step-offs to clue into underlying fracture.
 - To rule out Le Fort fracture, depress the maxilla bilaterally with your thumbs to feel for mobility. If mobile, proceed to grasp the maxillary teeth with one hand while holding the nasal spine in place with the other hand. Movement of the dental alveolus points toward a Le Fort I fracture, whereas movement of the nasal bridge points toward a Le Fort II or III fracture.
 - Check for involvement of deeper structures: muscle, nerve, artery, bone, joint.
 - Especially in bite wounds with fangs, the deeper structures may be injured.
 - Irrigation of the base of the wound provides more thorough visualization.
 - Sensory test for nerve involvement:

- V1 ophthalmic branch: provides sensation to the forehead
- V2 maxillary branch: provides sensation to the cheek
- V3 mandibular branch: provides sensation to the lower third of the face/chin
- Motor test for facial nerve involvement:
 - Test for weakness in the facial nerve (cranial nerve VII) quickly and effectively by asking the patient to raise the eyebrows, close eyes, smile, puff out cheeks, and evert lower lips.
- Assess for crepitus (subcutaneous emphysema) in bite wounds that would indicate an infection forming along the deeper fascial planes.
- Examine all wounds for foreign body contaminants.

IMAGING

- If facial fractures are suspected, a CT scan should be performed.
- Plain x-ray or CT scan is helpful in determining the presence and location of foreign bodies within the wound.
- Ultrasound may prove as a quick and reliable tool for locating foreign body without the side effects of radiation.

NONOPERATIVE MANAGEMENT

- Nonoperative, or nonsurgical, management may occur in cases with very superficial and noncontaminated lesions, where washout, debridement, and closure are not necessary.
- Small wounds may have a preferred aesthetic outcome when allowed to close secondarily.

SURGICAL MANAGEMENT

- It is important to emphasize to the patient that any full-thickness injury to the skin will result in a scar.
 - The type of scar that forms can be dependent on multiple factors and is largely based on genetic predisposition.
- To maximize the chance of forming a fine-lined scar:
 - Most wounds require irrigation and debridement and closure in layers.
 - An early and tension-free closure of lacerations is a main priority.
 - Aim to close the wound in the direction of Langer lines, the relaxed skin tension lines of the face (**FIG 4**).
 - Find Langer lines in younger patients by asking them to animate their faces; the resultant skin folds simulate Langer lines.

- Delaying closure beyond 8 hours may increase the risk of infection of the wound bed and compromise aesthetic results, as swelling obscures anatomical landmarks.⁴

Preoperative Planning

- Use emergency room anesthesia: create a comfortable environment for the surgeon and the patient.

FIG 4 • Relaxed skin tension lines are ideal vectors for final scar placement.

- Topical anesthetic
 - Eutectic mixture of local anesthetics (EMLA) cream, composed of a mixture of 2.5% prilocaine and 2.5% lidocaine, is widely present in the emergency room—its effect is directly dependent on the time the cream has been on the skin.

- Place cream on skin and cover with a Tegaderm (3M, St. Paul, MN) or other occlusive dressing for at least 45 minutes.
- This often will need to be supplemented with local injected anesthesia but is a useful start for pediatric cases in which there is high anxiety associated with the local anesthesia.
- Local injected anesthetics
 - Lidocaine: most commonly used form of anesthesia in the ED. Maximum safe dose is 4.5 mg/kg. Effect usually lasts for 2 hours.
 - Epinephrine 1:100 000 may be added to the lidocaine solution to prolong the duration of its effect (to 4 hours) and reduce the amount of local anesthesia needed by reducing its diffusion away from the wound.
 - When epinephrine is added to lidocaine, the maximum safe dose is raised to 7 mg/kg.
 - Epinephrine takes about 7 to 15 minutes to take effect.
 - It was previously believed that epinephrine should not be used around end arteries such as the nose and stellate lacerations but is now accepted as safe practice.
 - Bicarbonate may be added to local anesthesia in the awake patient to reduce the burning pain on injection by raising the pH of the acidic lidocaine solution.
 - Bicarbonate also increases the effectiveness of the local anesthetic by favoring the nonionized form of the molecule, which passes through the cell membrane more easily.
 - Add 1 cc of 1 mEq/mL bicarbonate for every 9 cc of local anesthetic.
 - Bupivacaine: a longer-acting anesthetic, which may be added to the solution per the surgeon's discretion
 - Max safe dose: 2.5 mg/kg. Effect usually lasts 4 hours. When epinephrine is added, max safe dose is raised to 3 mg/kg, and the effect is prolonged to 8 hours.
 - Improve comfort on injection: warm the local anesthetic solution, use a higher-gauge (smaller caliber) needle, inject through wound instead of through skin
- Nerve blocks
 - For large lacerations in a single nerve distribution, nerve blocks can be effective and reduce the tissue distortion, which results when a large amount of local anesthetic is given as a field block.

■ Conscious sedation

- Beneficial for pediatric patients who are uncooperative, making repair of facial lacerations difficult.
- Helps to make the repair safer and reduces emotional trauma to the patient.⁵
- This requires continuous monitoring of vital signs, requiring a nurse to be present throughout.
- For pediatric cases, a combination of ketamine and versed are commonly used.
- Ketamine: analgesic and amnestic agent
 - Pediatric dosing: 6 to 10 mg/kg PO once, 30 minutes prior to procedure; or 0.5 to 2 mg/kg IV once at start of procedure
- Versed: sedative-hypnotic and amnestic agent
 - Pediatric dosing: 0.25 to 0.5 mg/kg PO or IM 15 minutes prior to procedure; or 0.05 to 0.1 mg/kg IV 3 minutes prior to procedure

■ Irrigation

- Thoroughly irrigate all wounds to remove blood, foreign body debris, and bacteria.
- Use of a pressured irrigation system is helpful if available in the ED.
- May use 1-L bottle of normal saline with holes punched in the lid with an 18-gauge needle as a make-shift pressurized system.

■ Debridement

- Trimming of jagged skin edges with a 15-blade for optimal cosmetic closure.
- Debridement of devitalized skin and tissue will reduce contamination and facilitate healing.
- Be mindful of the location of your debridement, as heavy debridement in the critical areas in the face (eyelid, nose) may lead to significant disfigurement.

■ Hemostasis

- Use pressure, suture ligation such as Vicryl 4-0 (Ethicon, Somerville, NJ), Surgicel (Ethicon, Somerville, NJ), silver nitrate, thrombin, or fibrin. Electrocautery is now often available in the ED.
- Because of extensive collateralization of vessels in the head and neck, even major vessels such as the facial artery may be ligated if bleeding is uncontrolled.
- If bleeding is significant, you may extend the laceration to achieve visualization of the bleeding vessel.
- Do not blindly clamp tissues as this risks injury to nearby nerves and other

structures.

- If the bleeding vessel cannot be clearly visualized, the wound should be packed, pressure applied, and the patient should be brought to the operating room promptly.

Positioning

- Prior to beginning any procedure in the emergency room, ensure you have a well-lit and adequate space.
- Head of bed should be elevated on a pillow for head and neck lacerations.
- Pediatric cases may require “papoosing” of the child by nursing staff and may require that a family member present throughout the procedure.

Approach

- Wounds may be closed with sutures, staples, skin tape, or wound adhesive.
- Suture choice:
 - Absorbable for all deeper layers and for mucosa and pediatric epidermis
 - Nonabsorbable for suture ligation of large vessels and for epidermal approximation
 - Nonbraided (monofilament) material best for contaminated wounds

Table 2 Appropriate Suture Choice for Specific Facial Laceration Locations

Location	Suture Material ^a	Suture Size	Suture Half-life	Removal
Scalp Galea Skin	Vicryl/PDS Prolene or staples Or chromic gut	2-0 3-0	2–3 wk/4 wk Permanent 2 wk	Absorbable 7–14 d Absorbable
General face Muscle Deep dermal Epidermis	Vicryl/PDS Monocryl Nylon or Prolene	3-0 or 4-0 4-0 or 5-0 5-0 or	2–3 wk/4 wk 1–2 wk Permanent	Absorbable Absorbable 5 d

		6-0		
Eyelids Orbicularis Skin	Vicryl Nylon	6-0 6-0	2–3 wk Permanent	Absorbable 3–5 d
Ear Cartilage/skin	Nylon or Prolene	5-0 or 6-0	Permanent	5 d
Nose Cartilage Skin	PDS/clear nylon Nylon or Prolene	4-0 5-0 or 6-0	4 wk/permanent Permanent	Absorbable/permar 3–5 d
Lip Muscle Mucosa Vermilion border	Vicryl/PDS Chronic gut Nylon or Prolene	3-0 or 4-0 3-0 or 4-0 6-0	2–3 wk/4 wk 2 wk Permanent	Absorbable Absorbable 5 d
Intraoral mucosa	Chronic or Vicryl Rapide	3-0 or 4-0	2 wk	Absorbable
Pediatric skin	Fast absorbing plain gut	6-0 or 6-0	5 d	Absorbable

^aAll suture materials refer to those supplied by Ethicon, Inc. (Somerville, NJ).

- Taper/round needle ideal for muscle, fascia, mucosa
- Cutting needle ideal for skin
- Common emergency department suture choices available are as follows:
 - Muscle: Vicryl 4-0, Monocryl 4-0, PDS 4-0 (Ethicon, Somerville, NJ)
 - Skin:
 - Buried deep dermal layer: Monocryl 4-0 or 5-0
 - Superficial subcuticular layer: nylon/Prolene 5-0 or 6-0 (Ethicon,

Somerville, NJ)

- Mucosa: simple chromic/Vicryl Rapide 3-0 or 4-0 (Ethicon, Somerville, NJ)
- Pediatrics: simple fast absorbing plain gut 5-0 or 6-0
- Proper suture choice for specific anatomic locations of the face is imperative for maximizing healing and minimizing scar formation (Table 2).

TECHNIQUES

■ General Laceration Closure Techniques

- Simple interrupted: standard for closing all layers. Allows for optimal tissue reapproximation, especially in wounds with uneven lengths. Recommended for buried deep dermal and epidermal closure (**TECH FIG 1A**).
- Simple running: quicker means of closing epidermis in wounds with long length. Optimal for use in wounds where both sides evenly line up and there is no apparent “dog ear.”
 - Disadvantages:
 - Not as precise as simple interrupted stitch
 - Unintentional breakage of the suture will lead to separation of the entire wound
 - Need to remove entire suture length if infection develops postrepair
- Vertical mattress: optimal for eversion of skin edges, yet is widely known as the most ischemic suture method and may result in skin ischemia if placed too tightly.
- Horizontal mattress: particularly useful in thick glabrous skin.
 - Similar to the vertical mattress counterpart in that it is effective in everting skin but risks development of skin ischemia.
- Staples: optimal for fast and effective closure of scalp wounds. May be used in very contaminated wounds that need to be closed loosely.
- Adhesive skin tape: beneficial for very superficial and small wounds closed with minimal tension^{6,7}
 - Brief and painless procedure
 - Difficult to exactly approximate edges and maintain eversion of epidermis
 - Resulting scar similar to suture repair^{7,8}
 - Best for upper third of the face as this area is of least skin tension

- Dermabond: may be used for clean wounds closed with minimal or no tension.

TECH FIG 1 • A. Suture closure techniques. **B,C.** Ideal closure for reapproximation of edges is simple interrupted suture.

- In crush injuries where the extent of the damage is unclear, tissues can be loosely reapproximated.
- If flap is avulsed, it should be tacked down where it lies, so that the closure is tension free. If there is undue tension on the flap, chance of necrosis is high.
- Epidermis should be everted at the edges, as eversion will flatten out to create a flat scar. Skin that is not everted at closure may produce a concave-shaped scar.
- Deeper wounds that cannot be closed can be packed with normal saline wet-to-dry dressings or iodoform gauze packing strips. Exposed bone or neurovascular structures can be covered first with Xeroform.
- Burns and abrasions can be treated with Adaptic gauze and bacitracin or

with silver sulfadiazine.

■ Scalp Lacerations

- Two-layered closure:
 - Galea layer: use 2-0 Vicryl or PDS (Ethicon, Somerville, NJ) for tension-bearing layer.
 - Skin: use full-thickness continuous suture with 3-0 Prolene (Ethicon, Somerville, NJ) or staples.
 - Alternatively, can use 3-0 chromic as this does not requires suture removal
- Scalp defects fewer than 3 cm can usually be closed primarily.
 - Galea scoring may be necessary to gain laxity for closure.
- Attempt to prevent hair from being entangled in the sutures.
- May use Penrose drainage for first 24 to 48 hours (**TECH FIG 2**).

TECH FIG 2 • **A.** Laceration and partial avulsion of the forehead and anterior scalp. **B.** Galea layer reapproximated with Vicryl 2-0 (Ethicon, Somerville, NJ) and skin closed with interrupted nylon sutures.

■ Eyelid Lacerations

- First complete a full exam +/- ophthalmology consult to rule out ocular injury and lacrimal duct injury.
 - Jones I: instill fluorescein dye in the eye, wait 5 minutes, check for

drainage through ipsilateral nare.⁹

- Absence of fluorescein indicates nonfunctioning lacrimal system, and Jones II is performed.
- Jones II: irrigate residual fluorescein dye in the nasolacrimal system with saline and watch for reflux from the canaliculi or presence of fluorescein dye in the wound. Either finding indicates damage to lacrimal duct system.
- Proper alignment of all layers minimizes risk of lid notching, ectropion, and functional deficit.
- Three layered closure of conjunctiva, tarsus, and skin
- Orbicularis and tarsus: 6-0 Vicryl (Ethicon, Somerville, NJ).

TECH FIG 3 • Laceration of the eyelid margin requires everting vertical mattress suture into the tarsus to realign lid margin and prevent notching of the eyelid. After the eyelid margin is realigned, the remainder of the laceration can be reapproximated.

- Skin: 6-0 fast absorbing gut suture or 6-0 nylon.
- Keep all knots directed away from the cornea.
- If lid margin is involved, approximate the gray line and tarsal plate with everting vertical mattress suture to prevent notching of the eyelid (**TECH FIG 3**).
- Depth of suture: through skin and half way through tarsus
- Partial-thickness defects involving less than 50% of eyelid length can be closed with local advancement flaps. Involvement greater than 50% requires a skin graft harvested from the contralateral eyelid for a tension-free closure.⁹

- Full-thickness defects involving less than 33% of the upper lid and 50% of the lower lid can be closed primarily.
- More significant eyelid defects require flaps for closure.

■ Ear Lacerations

- Irrigate ear lacerations thoroughly to prevent possible chondritis.
- Debride skin conservatively to avoid cartilage exposure after closure.
- As long as the skin is still adherent to the cartilage, approximating only the skin in suture bites is sufficient for realignment of the cartilage. Use 5-0 or 6-0 Prolene (Ethicon, Somerville, NJ).
- Large defects with exposed cartilage should be covered with Xeroform petrolatum gauze dressing (Covidien, Mansfield, MA) with frequent dressing changes until reconstruction is completed.
- Avulsion injuries: should be promptly debrided, and small avulsion fragments less than 1.5 cm in width can be reattached as a composite graft in the first 12 hours. Large avulsions/amputation may require intraoperative microvascular replantation.
 - Venous congestion is a common problem following microvascular arterial anastomosis; postoperative leech therapy is commonly employed.
- Dress ear laceration with Xeroform gauze (Covidien, Mansfield, MA) and fluffed gauze in a pressure dressing with circumferential head wrap to avoid hematoma formation (**TECH FIG 4**).

TECH FIG 4 • A. Laceration of the ear through cartilage, with partially avulsed helical rim flap. **B,C**

Irrigated and closed with interrupted nylon sutures anteriorly and interrupted chromic sutures posteriorly.

■ Nasal Lacerations

- Nasal hemostasis may need to be achieved with either anterior or posterior nasal packing layered cottonoid or Xeroform gauze (Covidien, Mansfield, MA).
 - Septal nasal hematomas must be ruled out. If visualization of the septum is not clear, slide your small finger into each nostril for palpation of a bulging hematoma.
 - If septal hematoma is present, this should be drained under direct vision with an no. 11 blade.
 - Unlike ear lacerations, reapproximating the skin does not necessarily reapproximate the underlying cartilages, and lacerations should be addressed separately.
 - Use 4-0 Vicryl (Ethicon, Somerville, NJ) or clear nylon suture for cartilage reapproximation.
 - Use nylon or 5-0 or 6-0 Prolene (Ethicon, Somerville, NJ) for skin closure.
 - The traditional view of resecting an entire subunit of the nose if greater than 50% is compromised has been challenged in favor of retaining all native healthy tissue.
 - Defects of tissue may be repaired in the operating room with local flaps such as the dorsal nasal, nasolabial, and paramedian forehead flap.¹⁰
-

■ Lip Lacerations

- By taking care to align the “white roll” of the vermilion border, the outcome will be the most cosmetic. Differences in alignment of the white roll as small as 1 mm can be noticeable to the human eye at conversational distance.
- Align the white roll (vermillion-cutaneous junction), philtral columns, and cupid's bow before any injection with anesthetic to avoid distortion of these landmarks by the added volume of the anesthetic (**TECH FIG 5**).
 - You may mark these by tattooing with methylene blue.
- Primary closure can be accomplished when less than 30% of the lip is

involved in the defect.⁹

- Defects in the central upper lip may distort the anatomy of the philtral columns. The defect should be closed with the available lip tissue and may be corrected later.
- Closure of each layer of the laceration is necessary to maintain appropriate thickness of the lip throughout the laceration.

TECH FIG 5 • A demonstration of a lip laceration through the cutaneous-vermillion border. The first stitch for optimal reapproximation is at the level of the white roll (*white line*).

- Muscle: 3-0 or 4-0 Vicryl (Ethicon, Somerville, NJ)
- Epithelialized skin and white roll stitch: 6-0 nylon/Prolene (Ethicon, Somerville, NJ)
- Mucosa (lip surface): 3-0, 4-0 chromic suture

■ Facial Nerve Injury

- Any laceration in the path of the branches of the facial nerve should be explored for laceration of nerve (see **FIG 2**).
- Deep lacerations through the parotid gland are at high risk of nerve injury (**TECH FIG 6**).
- Repair of the lacerated nerve should take place as soon as possible and within 72 hours of injury.
- Repair delayed after 72 hours is difficult secondary to inability to stimulate

the distal end of the nerve due to depletion of neurotransmitters at the motor end plates and contraction of the cut segment of nerve.

- In the operating room and under magnification vision, the ends of the nerve should be trimmed and coapted tension free with 9-0 or 10-0 nylon epineural sutures.
- If repair cannot be completed without tension, consider nerve grafting or placement of a nerve conduit.

TECH FIG 6 • Laceration of preauricular region of the face, deep through parotid gland and lacerating the main trunk of the facial nerve as well as the parotid duct.

■ Parotid Duct Injury

- Evaluate a parotid duct injury by cannulating the intraoral segment with a 22-gauge Angiocath, and inject 1 cc of hydrogen peroxide, methylene blue, or milk into the duct. Blue dye (caution: messy!), milk, or foaming of hydrogen peroxide in the wound indicates a ductal injury.
- If the laceration appears to only involve gland tissue, the lacerated gland can be oversewn.
- Repair lacerated duct over a stent (red rubber catheter) using 7-0 nylon.
- Keep stent in place for 5 days with prophylactic antibiotics (**TECH FIG 7**).

TECH FIG 7 • A. Unrestrained child in motor vehicle collision with multiple significant lacerations and significant loss of tissue. Extensive debridement in the ED revealed multiple pieces of glass in the wound. **B.** After thorough irrigation, the wound was closed in layered interrupted fashion.

PEARLS AND PITFALLS

Preoperative planning

- Treat all bite wounds as contaminated wounds with thorough irrigation, debridement, and antibiotics.
- Small wounds may heal as well or better if left to heal secondarily.
- Always consider facial aesthetic lines when planning closure for optimal scar placement.
- Be aware that crush injuries can produce larger areas of damage than initially appreciated.

Irrigation

- Thoroughly irrigate all wounds; you can never overirrigate.

Debridement

- Debridement of devitalized skin will reduce contamination and improve healing.

Closure

- Be mindful of proper suture choice for each anatomic location.

- Alignment of skin edges is optimal with simple interrupted suture.
- Align critical regions (ie, the white roll of the vermillion border or the eyelid margin) first to minimize distortion of these regions.

Final outcome

- In addition to factors such as timing, technique, and suture material, healing has a large genetic component.

POSTOPERATIVE CARE

- One dose of IV antibiotics should be given in ED for all facial lacerations.
- If wound is grossly contaminated or patient is diabetic, send the patient home on an oral outpatient antibiotic regimen with MRSA coverage (clindamycin or Bactrim).
- Rarely, acute wounds will require IV antibiotic treatment.
- Subacute and severely contaminated wounds may require admission for IV antibiotics.
- Bite wounds should be treated as contaminated wounds in the acute setting and require anaerobic coverage.
 - First-line treatment for bite wound is Augmentin (875 mg PO bid × 7 days for adults, and 45 kg/d PO bid × 7 days for pediatric dosing).
 - IV therapy for bite wounds: first line is Unasyn (Pfizer, Inc., New York, NY) 1.5 g IV q6h.
- All wounds should be given care instructions for daily cleaning and bacitracin application TID until sutures are removed
- Tetanus prone wounds: greater than 6 hours old, contaminated or in contact with soil, puncture wounds, animal or human bites, largely devitalized, infected.³
 - Incompletely immunized or uncertain: full tetanus vaccine (if moderate- to high-risk wound, also give tetanus immunoglobulin)
 - Greater than 10 years since immunization: give tetanus toxoid (if high risk, give tetanus immunoglobulin)
 - Five to ten years since immunization: if moderate to high risk, give toxoid.
 - If less than 5 years since immunization: no need for booster

OUTCOMES

- In general, the high vascularity of the face results in good healing with a low infection and dehiscence rate.
- Final scar maturation is completed by 1 year postoperatively, and as aesthetic

appearance is always a concern to patients, maximizing aesthetic outcome should always be a priority

COMPLICATIONS

■ Infection

- Dog bite infection rates around 5% to 8% after ED washout^{3,11} (**FIG 5**).
- No change in incidence of dog bite infection rate between closure and nonclosure of wounds; therefore, approximation of tissues is recommended.¹²

■ Hematoma

- Auricular hematomas should be drained promptly through incisions in skin, and a compressive bolster dressing should be placed to prevent reaccumulation.

FIG 5 • Child presenting with cellulitis and abscess of the right cheek 48 hours after ED closure of dog bite wounds.

■ Sialoceles

- Unidentified laceration of the parotid gland or parotid duct may result in delayed accumulation of saliva, presenting as swelling and tenderness of one cheek. Treatment involves compressive dressing, and if drainage is required, perform I&D through intraoral route.

■ Chondritis

- Delayed onset of pain after ear laceration warrants prompt evaluation for chondritis. Cartilage is poorly vascularized, and infection requires IV

antibiotic therapy.

Section XX: Craniofacial Prosthetics

72 Craniofacial Anaplastology: Prosthetic Osseointegration

CHAPTER

Chad A. Purnell, Rosemary Seelaus, and Pravin K. Patel

DEFINITION

- Anaplastology derives from the Greek *ana* to make again, anew, upon *plastos*—something made, formed, molded *logy*—the study of art and science of restoring a malformed or absent part of the human body through artificial means.
- Prosthetic derives from Greek *prósthesis*, addition, application, attachment as an artificial device that replaces a missing body part that may be lost through trauma, disease, or congenital conditions.
- Prosthetic and autologous reconstructive techniques are complementary, and in many circumstances, both are required to achieve an optimal aesthetic outcome in the reconstruction of craniofacial defects.¹ Prosthetic reconstruction can result in significantly improved quality of life for patients when conventional reconstruction reaches its limits.^{1,2}
- Although autologous techniques remain the standard for long-term stable nasal and ear reconstruction, it frequently requires multistage surgical procedures with difficulty in achieving consistency of outcome and patient acceptability. Though the prosthetic approach can achieve consistency in outcome with minimal surgical intervention, it requires a lifetime of maintenance^{4,5} (Table 1). Each approach must be considered by having the patient and family involved in the discussion. However, in some instances such as orbital exenteration, ocular and periorbital prosthesis is the only option for the patient as no

autogenous alternatives exist.³

- Facial prosthetics can be either adhesive retained or fixed to osseointegrated implants. Other means of retention have been described but are less ideal. Due to disadvantages of skin reactions and less secure fixation with adhesives, implant-retained prostheses are most commonly used and result in the higher patient satisfaction.^{1,4}

Table 1 Comparison of Autologous vs Prosthetic Techniques for Facial Reconstruction

Autologous	Prosthetic
Often complex, multistage surgery	Minimal surgery
Reconstruction requires minimal maintenance once complete	Significant, lifetime maintenance
Can be higher risk for comorbid patients	Safer in patients with comorbidities
Wide range of reconstructive outcomes	Typically provides near-exact replication of anatomic structure
Own tissues used, late complications rare	Creates prosthetic-tissue interface, late complications more common

- *Osseointegration* derives from the Greek *osteon*, bone, and the Latin *integrare*, to make whole. The term refers to the direct structural and functional connection between living bone and the surface of a load-bearing implant.⁵ Osseointegrated implants may retain a prosthesis through magnets or through a bar-and-clip mechanism (**FIG 1**).

ANATOMY

- The placement of osseointegrated implants into the craniofacial skeleton requires an understanding of the bony buttresses of the face (**FIG 2**). These areas of greater bony strength provide adequate bone stock for implant placement.
- The patient-specific anatomy for cranial bone thickness and the mastoid region must be taken into consideration for placement of temporal bone osseointegrated implants and implants for bone conducting hearing amplification.
- Orbital prostheses are retained by the thickened bony rim of the orbit. Nasal

prostheses are retained by the thickened bony rim of the pyriform aperture.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Because of the extensive deformity whether of congenital, traumatic, or from tumor ablation, a multidisciplinary team tailored to the patient's needs will help in achieving the patient's goals with an understanding of what can and what cannot be achieved by surgical autologous and prosthetic approaches. The team ideally consists of a craniofacial surgeon, an anaplastologist, a psychologist, and in the case of auricular reconstruction and bone anchored implants, an audiologist and otolaryngologist are included. The psychologist plays a critical role in providing the supportive voice for the patient during the decision-making process and in the accepting of the outcome with their own expectations, which may not be technically achievable. Communication and educating the patient and family is critical.
- A history of the patient should be collected, with particular focus on the area to be reconstructed. History of pathology leading to tissue loss, prior reconstructive attempts and donor sites, and pathology that contributes to wound healing should all be elicited. This importantly includes a history of tobacco use, corticosteroid use, and radiation therapy.
- This examination should fully assess soft tissue quality and vascularity of the area to be reconstructed. Areas targeted for placement of implants must have stable and adequate soft tissue coverage.

FIG 1 • Magnet (*left*) and bar-and-clip (*right*) attachment methods for prostheses.

- Bone in areas for potential osseointegrated implant placement should be assessed for quality and areas of potential bone loss. This assessment is best done through skeletal imaging.
- The patient should be evaluated to determine the appropriateness of practical prosthetic use. This includes an evaluation of manual dexterity (to don/doff prosthesis), general personal hygiene, social support, history of compliance with medical treatment, and access to anaplastology services.

IMAGING

- Conventional 2D photography and 3D soft tissue imaging is ideal not only for documentation but for virtual design and planning of prosthetic implants.

FIG 2 • The craniofacial buttresses (shown in color) are areas of increased bony strength in the facial skeleton, which are the safest locations for implant placement.

- For straightforward placement of osseointegrated implants in the temporal/mastoid region in patients with normal bony anatomy, imaging may not be necessary. However, imaging is frequently necessary for symmetrical anatomical restoration and for virtual planning of the implants. CT or CBCT imaging is essential to evaluate bone depth and density, which may be abnormal. Areas of prior bony resection or reconstruction are evaluated carefully for residual bone. Bone quality is of paramount importance after radiation therapy, and abnormal anatomy in craniofacial syndromes should be noted.
- Preoperative 3D planning software that integrates the soft tissue and the underlying skeletal anatomy allows the simulated placement of screws into bone to determine ideal vectors and locations of placement (**FIG 3**). These technologies can be merged with intraoperative stereotactic guidance for particularly challenging cases to ensure optimal placement.⁶ At our center, we prefer to use a computer-generated guide for precise implant placement⁷ (**FIG 4**).

FIG 3 • Three-dimensional virtual planning for ideal implant placement.

SURGICAL MANAGEMENT

Preoperative Planning

- The number of implants to be placed should be decided with an anaplastologist to ensure adequate fixation. This decision will be affected by the location of the prosthesis as well as the type of fixation (magnet vs bar-and-clip). Magnet fixation may require additional implants to be placed.

FIG 4 • Custom 3D printed drill guide for precise implant placement.

- The anaplastologist, with the craniofacial surgeon, will prepare a template of the area to be reconstructed with implant locations designated to guide surgical placement. In the case of the ear, this template is usually made from the position of the contralateral ear and centered around the external auditory meatus or tragus if present.
- The implant depth is often decided prior to implant placement but can be decided intraoperatively based on clinical assessment of bone depth and density. Most craniofacial implant systems come in 3 and 4 mm depths.

Positioning

- Standard supine positioning with a head drape and general endotracheal anesthesia is used for most implant placements. For uncomplicated implant placement, some surgeons may prefer local anesthesia with sedation.
- Hair in the operative area is trimmed in a limited fashion.
- If surgical drapes will obscure visualization of a contralateral normal structure, marking should be performed prior to draping to ensure symmetry.

Approach

- A one- or two-stage technique can be utilized for implant placement. In a one-stage technique, the implant is positioned and an abutment is immediately placed through the skin. The one-stage approach is appropriate in a majority of scenarios.
- In a two-stage technique, skin is reclosed over implants capped with a cover screw. The implants are then allowed to integrate into bone (approximately 3 months). Exposure of implants and abutment placement occurs at a later stage. A two-stage approach is generally indicated if bone is irradiated or of poor quality, in children, or in the orbital or maxillary region.^{8,9} We typically favor a more conservative two-stage approach for many of our patients rather than early loading of the implant.

Osseointegration and healing time may range from 3 to 9 months depending on patient comorbidities and bone quality. This is typically based on intraoperative assessment.

TECHNIQUES

■ General Technique of Implant Placement

- Using the template created by anaplastology, the sites for implant placement are marked utilizing a needle dipped in methylene blue buried through skin and into bone.
- After a skin flap is raised (see specific anatomic areas for skin flap design), the skin is thinned to an ideal thickness of 2 to 3 mm (**TECH FIG 1A**). The skin flap is depilated through thinning or electrocautery of hair follicles or prior laser treatment. Periosteum is elevated (**TECH FIG 1B**).

A

- The sites for implant placement are identified. A guide drill with depth stop is used to drill a pilot hole in the correct vector (**TECH FIG 1C**). If the 3-mm depth stop results in complete drilling through bone, the 3-mm depth stop widening bit should be used and a 3-mm depth implant placed. If significant bone remains with the 3-mm depth stop, the 4-mm depth stop and implant can be used.
- A wider drill bit with countersink is used to widen and countersink the pilot hole at the appropriate depth.
- Outer table particulate bone is harvested and placed within the depth of the cranial bone at the dural interface when it is drilled full thickness.

TECH FIG 1 • **A.** Skin flap is thinned to an ideal thickness of approximately 3 mm. **B.** Periosteum elevated. **C.** Drill with depth stop at predetermined implant locations. **D.** The implant is tightened with a torque wrench. **E.** Biopsy Punch used to perforate skin at location of implants in one-stage technique.

- Implants are placed into the holes with a handpiece set at slow speed of 2000 rpm at 25 N-cm handpiece. The torque of 25 N-cm can be increased depending on the density of the bone.
- Tighten implant with torque device by the hand to recommended torque level of the implant system (**TECH FIG 1D**).
- At this point, if a one-stage technique is planned, a biopsy punch is used to make skin holes directly over each implant (**TECH FIG 1E**).
- Healing or standard abutments are placed into each implant in the one-stage technique.
- If a two-stage technique is used, cover screws are placed over each implant and skin is closed.

- The skin incision is closed in layers, including the periosteum.

■ Implants for Auricular Prostheses

- A skin flap is designed in the proposed area of implant placement by avoiding pre-existing scars if possible. Typically, this is an anteriorly based single flap encompassing the area of all implants. Implants are ideally placed 2 cm from proposed or actual external auditory meatus, at least 1 cm apart from each other, with at least one implant above and one below the meatus. Incision is planned 1 to 2 cm posterior to the implants (**TECH FIG 2A**).
- Two implants are usually adequate for fixation of a bar-and-clip prosthesis. These are placed within the confines of the planned ear prosthesis, with positions above, below, and posterior to the external auditory meatus¹⁰ (**TECH FIG 2B,C**).
- If an anchor for a bone-anchored hearing aid is to be placed, this is placed posterior to the planned auricular prosthesis into the temporal bone. If a magnetic-type implant is planned, it is 30 mm in diameter and thus must be located further from the ear.

TECH FIG 2 • A. Skin flap design for auricular prosthesis. Incision planned 1 to 2 cm posterior to planned implants, which are placed 2 cm from external auditory meatus, at 2 and 4 o'clock position, or 8 and 10 o'clock position. **B.** Auricular prosthesis. (*Left*) Contralateral native ear. (*Right*) Prosthetic reconstruction. **C.** (*Left*) Bar-and-clip mechanism of implant attachment. (*Right*) Prosthetic in place. (*Inset*) Prosthesis showing clips for attachment.

■ Implants for Nasal Prostheses

- Ideally, at least three implants are utilized for fixation of a nasal prosthetic.
- Incisions are designed to be hidden by the eventual prosthesis, and flaps are raised anteriorly and posteriorly (**TECH FIG 3A**).
- Good-quality bone is limited around the nasal cavity. The frontal process of

the maxilla (medial buttress) or premaxilla are sources of reasonable bone for fixation. The radix can also be used (**TECH FIG 3B**).

- Correlation with dental anatomy is essential to avoid the maxillary tooth roots if placing implants into the premaxilla.

TECH FIG 3 • **A.** Curvilinear incision used to access premaxilla for nasal implant placement. This incision will be completely hidden by the prosthesis. **B.** Implant locations for nasal prosthesis. **C.** (Left) Implants in place for magnet-retained nasal prosthesis. (Right) Prosthesis in place.

■ Implants for Orbital Prostheses

- Typically, three to five implants are adequate for fixation of an orbital prosthesis. Extra implants are often placed as it is assumed that an implant will be lost at some point.
- Incision is made at the orbital rim, under the area of the planned prosthesis. Flaps are raised in both directions from the incision, with the majority of the dissection deep to the rim (**TECH FIG 4A**).
- Implant location is generally designed in the superolateral orbital rim, if present, due to thicker bone in this area and for consideration of prosthetic appearance. If the lateral orbital rim is unavailable, the inferior and superior

rims are selected for implant placement. The medial orbital bone is thin and of limited utility for fixation (**TECH FIG 4B**).

- Longer length implants should be used if possible given higher rates of implant loss in the orbit.

TECH FIG 4 • **A.** Orbital exposure for implant placement. Note rim incision and subperiosteal dissection into orbit. **B.** Surgical planning for orbital implant placement. Lateral orbital rim is the location for the majority of implants. Multiple implants placed due to higher instability of orbital implants. **C.** (*Left*) Orbital exenteration defect with implants in place. (*Right*) Defect with prosthesis in place.

PEARLS AND PITFALLS

Communication/education	■ Educating the patient and family is critical to a successful outcome for the patient and for the treating team. Patients need to understand of the details of the steps involved to achieving the desired outcome. Expectations are best managed from the beginning. The psychologist and nurse are critical to this dialogue.
Implant vector	■ Implants should be placed to full depth and ideally perpendicular to both bone and soft tissue. ■ The guide drill must be used completely down to the depth stop to ensure proper seating.
Soft tissue contour	■ Soft tissue should be thinned in a gentle taper around the implant area to avoid a step-off.
Hair at site of implants	■ If hair remains after surgery, this can be treated with a laser depilation at a later time.
Postoperative maintenance	■ It is critical that patients with the support of their family establish a daily routine for the management of the peri-implant soft tissue and care of the prosthesis. Failure to provide adequate care will lead to loss of implant.
Follow-up	■ Patients with prostheses should be followed frequently at a minimum of an annual visit to assess the peri-implant tissue and the quality of the prosthesis. It is important for the team to assess its own outcomes and understand the patient's satisfaction or dissatisfaction with the treatment.

FIG 5 • Head wrap dressing used postoperatively after auricular implant placement.

POSTOPERATIVE CARE

- The area of reconstruction is covered with a pressure dressing and then a head wrap dressing (**FIG 5**), which is left in place for a period of 2 to 3 days. After this point, abutment site care is initiated and showering is permitted.
- The abutment site is cleaned daily with mild soap and a soft bristle brush to prevent crusting or buildup. Peri-implant hair should be trimmed and ideally removed permanently.
- If a one-stage technique is utilized, healing abutments are left in place for 10 to 12 weeks until the final abutment is positioned. In a two-stage technique, a period of 12 or more weeks is allowed for osseointegration. Once the final abutment is in place, the prosthesis fabrication can begin.

OUTCOMES

- Craniofacial implant–anchored prosthetics are well tolerated and have a long history of success. A majority of patients are able to wear their prosthesis for greater than 12 hours/d.^{1,11,12} Implant anchoring tends to improve patient-reported quality of life overall.
- Implant failure rates are low in nonirradiated patients, with failure rates of 5% to 20% in nonirradiated sites in long-term studies.^{7,11,13,14}
- Failure rates are higher in irradiated patients.¹⁵ Large studies have shown failure rates of 23% to 54% over time in irradiated fields.^{7,13,14,16,17} Studies are mixed on whether high-dose radiation increases implant failure rates over low-dose radiation.

- The role of hyperbaric oxygen (HBO) on implant survival in irradiated fields is as of yet unclear.¹⁵ Some studies suggest that HBO used after implant placement may decrease failure in irradiated bone,^{13,17} whereas others have seen no differences in outcomes.¹⁶
- Prostheses themselves have a limited life. Many studies cite a 2- to 5-year life span.¹⁸ However, prostheses may last significantly less time depending on the patient's tolerance of discoloration or level of activity with prosthetics in place due to tearing or damage.¹⁹

COMPLICATIONS

- The most common complication with osseointegrated implants are soft tissue–related reactions due to inflammation.^{15,20,21} Reactions are typically graded on a scale of 1 to 4 (Holgers scale). One is slight local erythema. Two is erythematous and slightly moist, 3 is moist with granulation tissue, and 4 is infection.²¹ Rates of reactions overall range from 3% to 26%, with grade 1 reactions being by far the most common.^{9,14,21} Device removal due to infection is extremely rare. The vast majority of skin reactions can be treated with medication. In cases of exuberant granulation tissue, local tissue around the abutment can be removed surgically (**FIG 6**). Aggressive thinning of peri-implant soft tissues at the time of placement in order to eliminate skin mobility around the implant is the best way of limiting peri-implant soft tissue reaction.

FIG 6 • Exuberant granulation tissue reaction around abutments.

- Implant failure can occur early because of inadequate osseointegration with

poor bone quality and can occur late due to chronic soft tissue infection affecting the peri-implant bone interface.

- During drilling for auricular implants, occasionally the dura of the middle cranial fossa or the sigmoid sinus will be exposed or perforated. In these cases, if bone stock is good, the implant can be placed as normal and the leak will seal. If the bone stock is poor, the leak should be sealed with pericranial tissue followed by autogenous particulate bone harvested from the same operative field and packed densely into the defect with fibrin sealant. The implant should be relocated.

Section XXI: Conjoined Twins

73

Conjoined Twin Separation

CHAPTER

Michael R. Bykowski, Joseph E. Losee, and Lorelei J. Grunwaldt

DEFINITION

- Conjoined twins are individuals who are physically connected by their anatomy and share one or more organs. The site of fusion and orientation of the twins characterize the different types of conjoined twins. Although some conjoined twins can live functional lives, surgical separation is often performed for religious beliefs, cultural beliefs, parental wishes, and/or to promote survival of one or both twins.
- Conjoined twin separation is the procedure of surgically dividing the conjoined twins, allocation and reconstruction of shared organs, and soft tissue coverage. The challenge of the complex anatomy and physiology requires comprehensive preoperative planning and coordination by a multidisciplinary team often lead by the plastic surgeon.
- Because there is great variability of fusion patterns of conjoined twins, surgical management cannot be reliably predicted and is not amendable to treatment within fixed protocols. As such, this chapter discusses the general key principles for planning and executing separation of conjoined twins.

ANATOMY

- The detailed anatomy of conjoined twins is dependent on each set of twins. In general, however, the larger the connecting bridge between twins, the more complex its contents.
- The tissues of conjoined twins are normal but the anatomy is not. The anatomy

is always abnormal but not in a reliably predictable manner. Nonetheless, there are general patterns to the anatomy based on the fusion type. The anatomical arrangements may be such that one twin may be incapable of independent existence.

- Classification is based on terminology according to the most prominent site of connection plus the suffix “pagus,” which is the Greek word meaning “that which is fixed”.¹ Some forms are described below:
 - Thoracopagus (40 cases; **FIG 1A**): junction primarily at the chest with varying amount of fusion of the heart, pericardium, and diaphragm.
 - Omphalopagus (34 cases; **FIG 1B**): joined at the abdomen and often have fusion of the liver and gastrointestinal (GI) tracts.
 - Pygopagus (18 cases; **FIG 1C**): connection at the sacrum/perineum and commonly face away from each other. May have fusion of the terminal spinal cord and associated meninges.
 - Ischiopagus (6 cases; **FIG 1D**): connected at the pelvic level. Each twin may have a normal leg and a common fused leg (ischiopagus tripus) or each has two normal legs (ischiopagus tetrapus). Often have fusion of distal small intestine/large intestine and genitourinary system.
 - Craniopagus (2 cases; **FIG 1E**): fusion of the skull and meninges. (The separation of craniopagus twins is often driven by the neurosurgical team and is not discussed in detail in this chapter.)

PATHOGENESIS

- Conjoined twins are monozygotic, monoamniotic, and monochorionic.
- There are two leading theories for the pathogenesis of conjoined twin formation.²
 - Failure of separation of the embryonic plate approximately 15 to 17 days of gestation
 - Union of two separate embryonic discs

NATURAL HISTORY

- Conjoined twinning occurs in 1.5 per 100 000 births.³
- Other congenital anomalies that are not related to conjoining frequently occur and impact survival with cardiac abnormalities occurring in greater than 60%.⁴

PATIENT HISTORY AND PHYSICAL FINDINGS

- The minimal diagnostic criterion is the fusion of some portion of monozygotic

twins.

- The main physical finding—ie, the site at which the twins are connected—provides insight to the internal anatomy. Predictable patterns of fusion occur and are associated with shared organs and organ abnormalities (see **FIG 1**).

IMAGING

- From the time of prenatal diagnosis to the time of surgical separation, imaging is the most important aspect of conjoined twin management.
- Prenatal and postnatal imaging evaluations are critical for predicting prognosis, obstetrical planning, medical management, and ultimately surgical separation.
- Conjoined twins can be first diagnosed by prenatal ultrasound by the 12th week of gestation.⁵
 - Specific diagnostic ultrasound findings include fixed position of the twin bodies on repeated examinations over time, lack of a separating membrane between the twins, and an inability to visualize a separation between the fetal bodies and skin contours.
- Once the presence of conjoined twins is diagnosed prenatally, further imaging is crucial to delineate the anatomy and extent of shared organs; both of which are important for obstetrical purposes and prognosis.
- Due to the high incidence of cardiac abnormalities, fetal echocardiography is the most important prenatal evaluation.
 - All conjoined twins (irrespective of the site of connection, but especially for those with a ventral union pattern)⁴ should undergo fetal echocardiography.
 - The degree of cardiac fusion and the severity of associated cardiac anomalies can help predict the postnatal viability and thus provide information for parental counseling.
- Prenatal computed tomography (CT) is useful to delineate the anatomic arrangement of the twins, primarily bony anatomy.
- Magnetic resonance imaging (MRI) is the best modality to provide the most detailed imaging of the fetuses as well as their associated anomalies and extent of union.
 - Ultrafast T2-weighted MRI sequences eliminate the need for maternal sedation and allow precise anatomical assessment of fetal organs avoiding the artifact due to fetal movement.
- Once the fetuses are determined to be viable and subsequently survive birth

and the neonatal period, elective surgery can be planned with a team approach and with repeat postnatal imaging (discussed in detail below under “Preoperative Planning”).

B

FIG 1 • Five most common classifications. **A.** Thoracopagus. **B.** Omphalopagus. **C.** Pygopagus. **D.** Ischiopagus. **E.** Craniopagus.

DIFFERENTIAL DIAGNOSIS

- Teratoma
- Lymphatic malformation

NONOPERATIVE MANAGEMENT

- In determining operative vs nonoperative management of conjoined twins, a pragmatic approach is necessary to balance:
 - What is technically feasible by the health care team.
 - The parental wishes.
 - The likely outcome for the children with or without separation. (The issue of parental consent is beyond the scope of this chapter.) The technical feasibility and prognosis are issues that depend on each other and are dictated by which organs are connected and the extent of their connections.
- An extreme example demonstrating successful nonoperative management of a set of conjoined twins is the famous Eng and Chang Bunker. These twins—born in Siam in 1811—gained notoriety while traveling with the Barnum & Bailey Circus under the exhibition name “Siamese Twins.” Despite their abdominal connection, Eng and Chang married sisters, fathered 22 children, and lived together for 63 years.
- Separation of conjoined twins is contraindicated in the following circumstances:
 - Thoracopagus twins with complex cardiac fusion
 - Craniopagus twins with extensive cerebral fusion
 - Separation that would result in physical disability, which is unacceptable to the parents. This is often associated with shared organ systems with compromise of one or both twins when the organ system is removed from one twin (often seen in parapagus, extensive ischiopagus, and craniopagus).

SURGICAL MANAGEMENT

- The discussion of this chapter focuses on elective separation, but the management of conjoined twins can be characterized as three distinct groups:
 - Nonoperative
 - Emergency separation
 - Elective separation
- The objective of the operation is to separate the conjoined twins while adequately allocating each individual with organs for survival and to obtain soft tissue coverage over the resulting defect. In general, the anatomy of the

junction and the shared organs and structures dictate the technical details of the procedure.

- A multidisciplinary approach is required along with frequent planning meetings, involving all of the staff necessary before, during, and after surgical separation.
- The staff should include nursing, neonatologists, pediatricians, critical care physicians, anesthesiologists, and a variety of surgical specialists. Because a critical factor in conjoined separation is soft tissue coverage, the plastic surgeon is often the team leader and coordinates all activity.
- Elective separation should be delayed until at least 2 months of age if possible.⁶ The timing of separation varies widely from 2 months to 2 years of age. The critical factor is to allow time for extensive preoperative planning and simultaneous medical optimization.
- Occasionally, conjoined twins require mechanical ventilation to preserve respiratory functioning toward the end of tissue expansion of the abdomen or thorax, as there may be decreased tidal volume from external compression.⁷
- Due to the varied anatomy of conjoined twins, it is usually not possible to follow a predetermined protocol for surgical separation. In general, the main steps of the procedure are as follows:
 - Exposure of shared organs
 - Division, allocation, and reconstruction of shared organs
 - Identification and ligation of cross-circulation
 - Abdominal wall reconstruction and wound closure with rotational flaps, previously expanded tissues, and skin substitute materials

Preoperative Planning

- Although the health care team is large and multidisciplinary, it must be clear that there is a lead surgeon who is in charge and makes the final decisions on preoperative evaluations and treatment.
- Conjoined twin separation is technically challenging due to the various organs that can be fused. The most important factor for successful separation is preoperative planning through postnatal multimodal imaging modalities.
- Postnatal imaging is the keystone of preoperative planning to, firstly, assess operability and, secondly, to understand the shared anatomy and help with surgical planning.
- Three features are key to determining survival and thus should be a focus of

preoperative planning:

- Major vascular connections
 - CT angiogram: this modality is necessary to visualize vascular connections.
- Management of the body wall closure: without adequate soft tissue coverage, the patient is at risk for exposure of viscera, evisceration, and sepsis. CT imaging allows sufficient assessment of the anticipated soft tissue deficiency and can help determine reconstructive options. If closure is too tight, cardiac and pulmonary functioning can be compromised. Therefore, additional soft tissue coverage needs to be created or temporizing measures must be employed.
 - Tissue expansion.
 - Mesh or dermal substitutes.
 - Rotational flaps can be used as an adjunct to tissue expansion and skin substitutes.
- Performance of both hearts after separation: cardiovascular performance after separation is not predictable given potential changes in cardiac functioning and changes in circulation.
- Even with extensive postnatal imaging, close monitoring and treatment in the intensive care unit is necessary.
- Because congenital anomalies (unrelated to conjoined twinning) are common,³ all patients regardless of the form of conjoined twin should undergo cranial ultrasound, abdominal ultrasound, CT, and MRI. Three-dimensional models can be created to aid in surgical planning.
- As stated above, each type of union is associated with specific structural abnormalities, so preoperative evaluation and planning will vary.
- Each organ system should be preoperatively evaluated in a systematic manner.
 - Cardiovascular system: due to the high rate of cardiac abnormalities in all forms of conjoined twins, all twins should undergo postnatal echocardiography to characterize cardiac anomalies. Thoracopagus twins should undergo electrocardiographic-gated cardiac CT or cardiac MRI for detailed assessment of cardiac anatomy.
 - Respiratory system: CT is performed to demonstrate the anatomy of the lungs and airways. Parapagus twins often have abnormalities of the tracheobronchial tree. Although the respiratory systems in thoracopagus and omphalopagus twins develop separately, there may be associated abnormalities (eg, hypoplastic lobes secondary to diaphragmatic hernia or

asymmetric chest union).

- **Hepatobiliary tree:** the number of gallbladders, liver, and pancreas should be known. Furthermore, liver vascularity and hepatic venous drainage for each twin must be ascertained. The liver is fused in all parapagus twins, most thoracopagus and omphalopagus twins, and less frequently in ischiopagus twins. Cross-sectional imaging will demonstrate the degree of fusion and visualize the intrahepatic vessels. MRI or CT scan with contrast injected into one twin can help to delineate the plane of liver separation. Overall, 25% of thoracopagus twins share a biliary system. Magnetic resonance cholangiopancreatography (MRCP) provides a detailed assessment of biliary anatomy.
- **GI system:** the length of the alimentary tract should be evaluated. Though laparoscopy or upper GI contrast studies have been used to evaluate bowel distribution, much of the anatomy can be determined and managed during the separation procedure by the general surgeons. The lower GI tract is shared most often in ischiopagus twins (70% of cases) and in 25% of pygopagus twins. Pygopagus twins often have varying degrees of rectal fusion and common anuses. Contrast enema along with MRI will demonstrate complex anorectal abnormalities.
- **Urinary tract:** imaging studies are performed to assess the number, reflux status, and anatomy of the kidneys, ureters, urinary bladders, and urethras. Cystograms can identify small fistulae not revealed by cross-sectional imaging. In 15% of pygopagus cases, the bladder is shared. Half of ischiopagus twins share pelvic organs.
- **Genital system:** in pygopagus and ischiopagus twins, vaginoscopy is mandatory to assess vaginal and cervical anatomy. MRI can demonstrate the number of uteri, ovaries, vaginas, and testes.

FIG 2 • Markings prior to chest and abdominal tissue expander placement and subsequent removal due to restrictive lung disease.

- Central nervous system: the nature and extent of spinal cord fusion is assessed in pygopagus, ischiopagus, and parapagus twins with spinal MRI.
- Integumentary system: the soft tissue deficiency that will occur following separation can be estimated with CT scan. This information can be used to plan for the number of and placement of tissue expanders. Vascular territories of the skin can be mapped by intravenous fluorescein dye.
- Musculoskeletal system: CT scan provides detailed assessment of bony anatomy, which is especially useful to determine pelvic and spinal bony anatomy in cases of caudal union. MR angiography can be used as an adjunct to determine blood supply when vascularized muscle flaps are planned—eg, when a shared limb will be used for wound closure.
- The primary goal of the plastic surgeon is to provide coverage overlying the newly created defect following separation.
- Tissue expanders have been placed intraperitoneally and in subcutaneous positions throughout the bodies of conjoined twins.
- The size of the defect following separation can be extensive and require multiple strategies in addition to tissue expanders, including meshes or dermal substitutes.
 - Tissue expansion overlying the abdomen/thorax can compress the compliant

chest wall and immature respiratory muscles of young children, leading to restrictive lung disease⁷ (**FIGS 2 and 3**). As such, tissue expanders should be minimized around the thorax (**FIG 4**).

FIG 3 • Top row. CT cross-section view through ischiopagus twins with and without tissue expanders. **Bottom row.** Line drawing of chest cavity showing deformation of anterior chest wall with tissue expanders in place. (*Left*) Preoperative chest CT scan. (*Center*) Chest scan with tissue expanders inflated and resultant chest deformation. (*Right*) Chest scan 6 months after tissue expander removal and resolution of clinical respiratory symptoms.

FIG 4 • Tissue expanders removed for the chest of one twin but maintained in the other. A tissue expander is placed on the left extremity.

- When plausible, expanders should be placed near the pelvic ring so that counter pressure is provided to optimize tissue expansion. Caution must be taken to avoid expanding too rapidly to avoid skin ischemia and expander exposure.
- Due to the thin subcutaneous layer in infants, smooth wall tissue expanders are used. Textured implants tend to minimize capsule formation, which can promote thinning of the skin.
 - Distant ports are used rather than integrated ports. The reason is that the thin skin overlying the expander is more prone to breakdown from repeated injections during the expansion process.
- Tissue expansion using pneumoperitoneum is an alternative. Sterile air is injected (500–1500 cc) every 3 days to expand abdominal circumference.⁸ Ischiopagus tripus twins present with an accessory hip joint and lower extremity, giving a tripod, or “tripus” configuration. As discussed below in “Techniques,” the tripus (**FIG 5**) can provide additional coverage by filleting it open for maximal use of the skin, subcutaneous tissues, and muscle.

Positioning

- Positioning will depend on how the twins are conjoined. Due to the potential

for a long duration of surgery, the twins must be well padded to prevent the development of decubitus wounds.

- Positioning must allow adequate exposure to the planned line of separation.
- If a posterior approach is favored, position the patient supine initially. Once intubated and venous access secured, the twins can be turned prone. This maneuver can be cumbersome. Circumferential sterile surgical preparation is often required.

FIG 5 • Posterior view of the conjoined twins that demonstrates the tripus (after bones removed), which will be used for the abdominal wall reconstruction.

- An important consideration is that a separate room is prepared and staffed for once the separation is completed. One twin will be transferred from the initial operating room to the other room while final reconstruction and wound closure is performed for each. After separation, each individual should have its own anesthesia team, surgical team, surgical staff, and operating room.
- A staff member is assigned to communicate ongoing progress of the surgery and coordinates patient transfers.

Approach

- An anterior approach is most often performed.
- Depending on the conjoined twin anatomy, some surgeons favor a posterior

approach.

TECHNIQUES

■ Separation of Ischiopagus Conjoined Twins

Outline and Order of Procedures

- Anterior incision extending from the chest to perineum.
- Anterior pelvic osteotomy and “booking open” of fused pelvic ring.
- Ligation and reimplantation of twin no. 1’s left ureter.
- Transabdominal liver separation.
- Separation of two ileums from the single channel into the colon.
- Posterior pelvic osteotomy with excision of the extranumerary hip joint of the tripus.
- Fillet of the tripus to create two musculocutaneous flaps.
- Repair of ventral abdominal wall and pelvic floor defects with allograft, tissue expanded advancement flaps, and musculocutaneous flaps for each twin.

Initial Steps

- Plan the skin incision to provide optimal exposure of the shared internal organs to facilitate equal allocation and reconstruction of organs. Special attention is paid to the pelvic region where the most complex connection occurs between the gastrointestinal and genitourinary tracts.
- Markings: while the twins are supine, mark the most cephalad point at the junction between the twins. Extend the marking inferiorly along the midline (in line with the umbilicus) toward the pelvis. The marking continues to the left of twin no. 1’s labia majora, which was preoperatively determined to go with twin no. 1 (**TECH FIG 1A**).
- Sharply incise the ventral surface along the midline through the skin between the tissue expanders (**TECH FIG 1B**).
- Continue the incision deep through subcutaneous tissue with electrocautery to enter the abdominal cavity. Continue dissection inferiorly to the pelvic region to directly expose the anterior aspect of the pelvic ring. Note: it is known from preoperative imaging that the pubic symphysis is near-normal

and midline.

TECH FIG 1 • **A.** Inferior view of the twins demonstrating the markings about the perineum. **B.** The ventral incision is performed along the midline to provide adequate exposure of internal anatomy. **C.** The conjoined livers are exposed and separated with electrocautery and ligation of small venous branches that traverse the isthmus. **D.** The small soft tissue

bridge is the only connection of the twins. **E.** These soft tissues are separated, and the twins are entirely separate. **F.** The tripus of each twin is rotated medially and laterally and tacked down to be used for pelvic reconstruction.

- The urologists dissect, identify, and retract the ureters and bladders to prepare for safe division of the anterior pelvic ring at the pubic symphysis.
- In conjunction with the orthopedic surgeon, the pubic symphysis is visualized and divided using a combination of electrocautery and an osteotome. This maneuver allows the pelvis to “book” open.
- With this exposure, dissection is carried posteriorly toward the rectum, which appears to have two blood supplies, one from each twin.
- With focus moved more proximally, it is ascertained that each twin has an entire length of small bowel to near the distal end where there is a common channel of small bowel that leads into a single colon.
- Attention is directed to the anterior chest where dissection is carried down deep between the chest cavities of both twins. Dissection is continued along this plane to the posterior aspect of the twins toward the operating table.
- The connected livers are now adequately exposed, which are fused at the midline for a broad segment encompassing an approximately 8-cm span. The shared liver is separated with electrocautery and ligation of small venous branches that traverse the isthmus with 3-0 Vicryl sutures (**TECH FIG 1C**).
- Once the liver is divided, each twin’s liver, stomach, and proximal small bowel can be easily retracted to the right and to the left to identify the four kidneys in the retroperitoneum.
- A Balfour retractor is placed to give adequate exposure.
- Attention is then turned to separate the small bowel. At the level of the Meckel diverticulum, an EndoGIA stapler is fired across twin no. 2’s small bowel who will later undergo creation of an end ileostomy.
- Twin no. 1’s small bowel, colon, and colonic mesentery are separated from twin no. 2’s small bowel. A bulldog clamp is used to assess the vascularity of the colon, which is determined to have two separate active blood supplies. The colonic blood supply of twin no. 2 is divided because she will not have a colonic conduit.

- Of note, because twin no. 1 had more of the perineum, it was preoperatively decided to leave the rectum with twin no. 1.
- The colon is retracted laterally to allow the urology team to proceed. The balloon in each bladder is palpated to determine its location in the shared pelvis. Twin no. 2's left ureter, which connects to the contralateral twin's bladder, is ligated with 3-0 Vicryl at the ureterovesical junction.
- Dissection is performed to create definition between the bladders.
- Dissection is continued to isolate the uterus, fallopian tubes, and ovaries of each twin with their respective pedicles. This dissection further delineates the plane of cleavage for the twins.
- The previously ligated ureter of twin no. 2 is tunneled through the mesentery, spatulated, and closed to the neohiatus of the bladder. Good efflux of urine is confirmed, and the bladder is irrigated easily.
- After genitourinary reconstruction, attention is turned to the bony pelvis as it is still connected at the posterior aspect along with the extranumerary hip joint of the tripus.
- From preoperative evaluation, the iliac vessels are known to feed the conjoined connection within the single nonfunctional tripus.
- Using an abdominal retractor, the organs of each twin are retracted laterally to provide access to their medial shared hip structures and components.
- The aortas are palpated, and the iliac vessels of each child are identified and followed, which lead to either side of the hip joint. With the help of the orthopedic surgeon, osteotomies are created on either side of the hip joint, which is then excised.
- The distal portion of the femur was previously removed in a separate procedure due to concerns with pressure necrosis on adjacent tissue expanded skin. The proximal femur is then directly visualized and is grabbed with a towel clip. The proximal femur is skeletonized with electrocautery and removed in continuity.
- After the removal of the hip joint and the proximal femur, further dissection of the iliac vessels is performed as they course into the tripus internally. The dissection of the iliac vessels is performed cautiously with a handheld Doppler device until each set of iliac vessels is traced into the tripus. The tripus is then split longitudinally to create two individual musculocutaneous axial pattern flaps.
- At this point, a small soft tissue bridge only connects the twins (**TECH FIG**

1D). These soft tissues are separated, and the twins are entirely separate (**TECH FIG 1E**).

- The tripus of each twin is rotated medially and laterally and tacked down to be used for pelvic reconstruction (**TECH FIG 1F**).
- A patient bed is brought into the operating room, and twin no. 2 is transferred to the adjacent operating room where further reconstruction is completed.

Twin no. 2

- The procedure begins with the inset of the tripus, which is on the posterolateral right side of her lower body. The hemitripus is reflected as a musculocutaneous flap from lateral to medial at the inferior aspect of her ventral wound recreating her pelvic floor. The hemitripus is inset into the inferior edge of the wound initially into layers closing the deep soft tissues with 2-0 Vicryl (Ethicon, Inc., Somerville, NJ) in interrupted buried fashion followed by a single closure utilizing 3-0 Monocryl (Ethicon, Inc., Somerville, NJ) in an interrupted buried deep dermal fashion.
- The left upper leg expander, left chest wall tissue expander, and right upper chest wall tissue expander are removed to create the left leg inferiorly based advancement flap. This flap is elevated in the subfascial plane while also harvesting the capsule. The composite tissues are advanced centrally toward the ventral defect.
- On the left lower lateral abdomen, a wide-based rotation flap is created from removal of its tissue expander, which is rotated medially. Similarly, on the right upper posterior chest, the tissue expander is removed to create a wide-based rotation flap, which is based superiorly and rotated centrally.
- A large sheath of extra thick AlloDerm is used to close the fascial defect of the ventral body. The AlloDerm is inset to the surrounding fascia and body wall utilizing 2-0 PDS (Ethicon, Inc., Somerville, NJ) in a horizontal mattress fashion.
- On the inferior aspect of the ventral defect, the tripus remnant is used to recreate the pelvic floor by suturing muscular elements of the tripus to the surrounding remnants of the muscular pelvic girdle.
- The advancement flaps are closed in layers utilizing 2-0 Vicryl in an interrupted buried fashion within the deep tissues followed by skin closure utilizing 4-0 plain gut in a simple running fashion.

- The ventral defect is decreased in size using a no. 1 Maxon (Ethicon, Inc., Somerville, NJ) suture along the periphery of the closure to create a purse-string effect.
- The general surgeons re-entered the case to create a left-sided ostomy by incising the AlloDerm. The end ileostomy is brought through the left abdominal wall.
- A negative suction-assisted closure device is placed on the skin defect area directly atop the AlloDerm.
- The patient is transferred to the intensive care unit. Over the oncoming weeks, the vacuum-assisted suction device is used to promote formation of granulation tissue (**TECH FIG 2**).

Twin no. 1

- As with twin no. 2, the split tripus is used as an axial-based musculocutaneous flap for pelvic floor reconstruction. A large piece of 16 × 20-cm AlloDerm is sewn across the abdominal wall to act as a barrier and also to act as a substitute for the anterior rectus sheath.
- The four tissue expanders were removed. The expanders from the anterior chest and the lateral chest wall are used as advancement flaps.

TECH FIG 2 • Postoperative photograph of twin no. 2 showing healing of soft tissue defect.

- Back cuts are made along the lateral abdominal wall into the right axilla and also into the left axilla in the left lateral chest wall. These flaps are advanced into the middle and are sutured to each other.
- A large central defect remains that measures 10 × 15 cm where the AlloDerm is exposed. A negative suction-assisted closure device is placed atop of the exposed AlloDerm.
- The patient is transferred to the intensive care unit. Over the oncoming weeks, the vacuum-assisted suction device is used to promote formation of granulation tissue (**TECH FIG 3**).

TECH FIG 3 • Postoperative photograph of twin no. 1 showing healing of soft tissue defect.

PEARLS AND PITFALLS

Preoperative imaging

- Images obtained without anesthesia can be suboptimal. CT scans under general anesthesia allow suspension of respiration to minimize artifact.
- An additional benefit is that the anesthesia team has an opportunity to assess how each twin behaves hemodynamically while under general anesthesia.

Abdominal closure	■ Primary closure of the abdomen should be completed under no tension, as tension can lead to cardiopulmonary insufficiency and death. ■ A combination of techniques should be used to obtain tension-free closure, including tissue expanders, pneumoperitoneum, dermal replacement materials, and/or meshes (as a temporary measure).
Abdominal tissue expansion	■ Use of tissue expanders overlying the abdomen can be used to achieve skin expansion and coverage of moderately sized soft tissue defects. However, additional measures are often required such as rotational flaps and/or dermal replacement materials. ■ Tissue expanders should be placed near the pelvic ring to provide counter pressure to optimize soft tissue expansion.
Thorax tissue expanders	■ Circumferential placement of thorax expanders can lead to restrictive lung disease. This problem is especially true in younger patients with more compliant chest walls and immature respiratory muscles. ■ Restriction of respiratory mechanics is more pronounced in twins who are joined at the chest, which results in compressive forces on three of the four sides of the chest wall.
Pressure relief	■ A pressure relieving bed is critical to reduce decubitus ulcer development. ■ Pressure relief is paramount, especially with use of posterior tissue expanders, to avoid soft tissue necrosis and expander exposure.
Tripus fillet procedure	■ The third leg in ischiopagus tripus twins is deformed and nonfunctional and can even induce pressure necrosis to adjacent soft tissues undergoing expansion. ■ The filleted tripus can be separated to create musculocutaneous flaps for each twin for abdominal and/or pelvic floor reconstruction.

POSTOPERATIVE CARE

- Planning of postoperative care occurs in the preoperative period. Meticulous supportive care in the intensive care unit is mandatory. The acute physiological changes occur after separation, especially when cardiac separation is performed and/or extensive cross-circulation is present prior to separation.
 - Cardiovascular instability should be anticipated.
- In most cases, elective paralysis and mechanical ventilation is necessary for 24 to 48 hours for cardiopulmonary stabilization.
- Aside from critical care support, attention should be focused to promote wound healing.

- Nutrition must continue to be optimized postoperatively.
 - Parenteral and enteral feeding should be considered.
- Focus should be to reduce the risk of health care–associated infection with the strict use of gowns and gloves to decrease exposure to hospital pathogens.
- Pressure-relieving beds are required for wound healing and to prevent development of decubitus ulcers.
- Extremity immobilization can promote flap healing and can prevent accidental trauma induced by the moving infants.

OUTCOMES

- Patient outcomes depend on the extent and complexity of the connection of the conjoined twins.^{9,10}
- Omphalopagus twins typically have the least extensive connection and have the highest survival rates.
- Due to complex cardiac connections and abnormalities, thoracopagus twins have the lowest survival rates, with the exception of craniofacial anomalies.¹⁰

COMPLICATIONS

- Tight closure of the abdomen or thoracic cavities can lead to cardiopulmonary insufficiency, which can lead to abdominal compartment syndrome, restrictive lung disease, or a cardiac low-output state.
- Wound healing complications are common postoperatively.
 - Tissue necrosis can occur with high-tension closure, especially due to unpredictable blood supply of soft tissues.
 - With inadequate soft tissue coverage or subsequent breakdown, abdominal viscera can be exposed.
